Encoded latent membrane protein 1 of Epstein-Barr virus on follicular dendritic cells in residual germinal centres in Hodgkin’s disease

Abstract

Aims—To determine if there is an association between Epstein-Barr virus (EBV) infection and Hodgkin’s disease.

Methods—Fifty cases of Hodgkin’s disease and 25 reactive lymph nodes were screened for the presence of EBV-RNA (EBER) using in situ hybridisation, and for the expression of EBV encoded latent membrane protein 1 (LMP-1) by immunohistochemistry.

Results—In 42% of the cases of Hodgkin’s disease, EBER was detected in the nuclei of the malignant cells, and in LMP-1 expression was found 36%. Both EBER and LMP-1 positivity were seen in 34% of the cases. An additional finding was the presence of LMP-1 on follicular dendritic cells in residual germinal centres in two cases of Hodgkin’s disease. EBER was not detected in these germinal centres. In reactive lymph nodes only occasional EBER positive, small, lymphoid cells were found, without LMP-1 expression.

Conclusions—These results show a strong correlation between the presence of EBER and the LMP-1 expression in the Reed-Sternberg cells. They corroborate a role for EBV in at least some cases of Hodgkin’s disease. LMP-1 is probably presented as an immune complex in the germinal centres, as part of an immune response against EBV.

(J Clin Pathol 1994;47:29–32)

There is increasing evidence for an association between Hodgkin’s disease and Epstein-Barr virus infection (EBV). EBV-DNA has been detected in specimens of Hodgkin’s disease using Southern blotting. The EBV genomes present in these cases seemed to be of monoclonal origin, suggesting infection early in development of the disease. Using a very sensitive EBV-RNA in situ hybridisation technique, EBV-RNA (EBER) was found in Reed-Sternberg cells and its variants in nearly 50% of the cases. Furthermore, in 39–48% of the cases of Hodgkin’s disease, EBV encoded latent membrane protein 1 (LMP-1) expression can be detected only in Reed-Sternberg cells and their variants. LMP-1 is thought to have a role in EBV induced cell transformation and is expressed in several EBV associated malignancies. Little is known about a specific immune response to the EBV positive malignant cells in Hodgkins disease.

In this study we screened 50 specimens of Hodgkin’s disease for the presence of EBV-RNA (EBER) and for the expression of LMP, to determine the correlation of both EBV gene products. Special emphasis was given to EBV infection in the pre-existing lymph node component.

Methods

Formaldehyde fixed, paraffin wax embedded lymph nodes from 50 patients with Hodgkin’s disease and 25 reactive lymph nodes were studied. In two cases of Hodgkin’s disease snap frozen material, stored at −80°C, was also studied. Specimens of Hodgkin’s disease comprised one case of lymphocyte predominant Hodgkin’s disease (LPHD), 32 cases of nodular sclerosing (NSHD), 16 cases of mixed cellularity type (MCHD), and one case of lymphocyte depleted (LDHD), according to the Rye classification. The non-malignant lymph nodes displayed histologically non-specific reactive features with either predominantly follicular or interfollicular hyperplasia.

For in situ hybridisation a fluorescein conjugated DNA-oligonucleotide mixture of two 30-mers was used, complementary to the two nuclear EBER-RNAs encoded by EBV (Dakopatts (Dako), Glostrup, Denmark). RNA in situ hybridisation was performed on 6 µm tissue sections, placed on organosilane pretreated glass slides. After dewaxing and rehydration the sections were pretreated with proteinase K (3 µg/ml in phosphate buffered saline (PBS) for 30 minutes at 37°C. The slides were dehydrated again. One to two drops (15–30 µl) of EBV (EBER) oligonucleotides/fluorescein isothiocyanate (FITC) (undiluted; Dako) were added and covered with a coverslip for two hours at 37°C. The coverslip was removed and the sections were immersed in PBS. After preincubation with 10% normal swine serum a three-step peroxidase reaction was applied: the first step included mouse anti-FITC (Dako). The second, rabbit anti-mouse immunoglobulin, and the third, swine anti-rabbit immunoglobulin, both conjugated to horseradish peroxidase (both from Dako). Sections were counterstained with haematoxylin.

Immunohistochemical staining was performed on 6 µm tissue sections that were placed on organosilane pretreated glass slides. After dewaxing, endogenous peroxidase activity was blocked by incubating the slides in...
Several cases of both MCHD and NSHD showed positivity for EBER in a few scattered small lymphocytes. In some of these cases the malignant cells were negative. In four reactive lymph nodes occasional EBER positive small lymphoid cells were also detected.

Results
EBV-RNA (EBER) was found in 21 (42%) cases of Hodgkin’s disease and was restricted to the nuclei of Reed Sternberg cells and their variants. In MCHD 13 (81%) cases contained EBER; only eight (25%) cases of NSHD were positive. In contrast to LMP-1, several cases of both MCHD and NSHD showed positivity for EBER in a few scattered small lymphocytes. In some of these cases the malignant cells were negative. In four reactive lymph nodes occasional EBER positive small lymphoid cells were also detected.

Discussion
EBV was present in 42% of the patients with Hodgkin’s disease. EBV-RNA was predomi-
nantyly detected in malignant Reed-Sternberg cells. Furthermore, in most of the EBV positive cases of Hodgkin’s disease, Reed-Sternberg cells expressed the EBV protein LMP-1. We found a strong correlation between LMP-1 expression and EBER positivity in Reed-Sternberg cells and variants. As EBER positivity in small B cells can be detected in healthy people with EBV infec-

tion, it probably does not contribute to Hodgkin’s disease. Lack of LMP-1 expression in these cells supports this idea. These findings are consistent with those of other studies and suggest a pathogenetic role for EBV in Hodgkin’s disease. MCHD (75%) showed a stronger association with EBV than NSHD (25%).

The detection of LMP-1 expression in follicular dendritic cells in the germinal centres of two cases of Hodgkin’s disease has not been described before. There are two plausible explanations for this phenomenon. First, LMP-1 expression on follicular dendritic cells may be a reflection of the presence of EBV in these cells. Follicular dendritic cells show strong expression of CD21. The monoclonal antibodies clustered in CD21 include antibodies against the C3d receptor (CR2) present on B cells. EBV infection of B cells follows after specific binding to this receptor. Some of the monoclonal antibodies against CD21 (HB5 and anti-B2) have been found to react with related, but not identical, antigens, expressed on epithelium of the uterine cervix and oropharynx. As EBV can regularly be detected in these epithelia, this surface molecule on epithelial cells may serve as an EBV receptor. The association of the virus with Burkitt’s lymphoma, with B cell lymphoproliferative disorders, and hairy cell leukaemia in immune deficient patients, and with nasopharyngeal carcinoma concurs with this theory. CD21 expression has been found on Reed-Sternberg cells and variants containing EBV-DNA. If the follicular dendritic cells in the two cases of MCHD were infected by EBV a positive EBER in situ hybridisation signal would be expected, but we were not able to detect EBER positivity in these germinal centres in serial sections. Therefore, infection of follicular dendritic cells by EBV is not very likely.

The second, more plausible, explanation of LMP-1 expression on follicular dendritic cells is that the latter are believed to play an important part in the retention of antigen in lymphoid follicles and in the generation of B memory cells by binding of antigen-antibody complexes and presentation of these complexes to the follicular B cells. As the Reed-Sternberg cells and variants strongly expressed LMP-1 in these two cases of MCHD, it is conceivable that the follicular dendritic cells were binding the LMP protein in germinal centres in the form of an immune complex. This might have been an antibody response to EBV, directed against the LMP-1-antigen.

The malignant cells in Hodgkin’s disease are believed to express only part of the EBV latent proteins—EBNA-1 and LMP-1—and probably LMP-2. Antibody cocktail CS1-4 is directed against LMP-1 and does not react with LMP-2a or LMP-2b. The expression of LMP-2 on Reed-Sternberg cells has not yet been demonstrated by immunohistochemistry. Although foreign protein is expressed on relatively few malignant cells (Reed-Sternberg cells and variants) in a

prominent number of cases of Hodgkin’s disease, the immune system does not seem to be able to deal with these cells, despite the huge reactive lymphoid infiltrate surrounding these cells. Cytotoxic T lymphocytes are the most important defense system against viral infected cells, but EBNA-1 does not seem to be a suitable target antigen for cytotoxic lymphocytes.10 The cytotoxic lymphocytes response against LMP-1 is more complicated and does not seem to be present in everyone.11 LMP-2 probably is the most important target for cytotoxic lymphocytes but patients with Hodgkin’s disease are known to have an impaired immune surveillance. Whether antibody response to LMP-1 contributes to the defense against EBV positive cases of Hodgkin’s disease remains to be investigated.
