Hodgkin’s disease in a patient with common variable immunodeficiency

C Christopoulos, Th Papadaki, P Vlavianos, G Kokkini

Abstract
A 61 year old man with long standing common variable immunodeficiency presented with pyrexia, anaemia and leucopenia. A diagnosis of Hodgkin’s disease of the bone marrow was made. The typical histopathological and immunophenotypic appearances were clearly distinct from those of T cell lymphoma with Reed-Sternberg-like cells which, in contrast to Hodgkin’s disease, is a known complication of common variable immunodeficiency. Complete clinical and histological remission was achieved with combination chemotherapy. The latter was complicated by severe myelosuppression, unusually severe erosive mucositis and viral retinitis.

Keywords: Hodgkin’s disease, common variable immunodeficiency, hypogammaglobulinaemia.

Common variable immunodeficiency (or late-onset/acquired hypogammaglobulinaemia) is a pathogenetically heterogenous entity characterised by failure of B lymphocytes to produce antibody. T cell dysfunction coexists in many cases and it has been suggested that the primary abnormality is failure of T cells to promote and regulate B cell differentiation. There is a wide spectrum of clinical manifestations, including an increased incidence of malignant neoplasms, the commonest being lymphoproliferative tumours and gastric carcinoma. The lymphatic malignancies are usually non-Hodgkin’s lymphomas. Because of the relative rarity of the underlying disorder, little is known about the natural history and response to treatment of lymphoma in this particular setting, although there have been reports of successful use of chemotherapy. Here, we present a case report of Hodgkin’s disease developing in a patient with common variable immunodeficiency, which highlights the unusual anatomical localisation and problems associated with the clinical management of this condition.

Case report
A 61 year old man with common variable immunodeficiency was admitted to hospital for investigation of persistent pyrexia. He was known to have splenomegaly (reported to occur in up to 28% of patients with common variable immunodeficiency) since the age of 30 years, and mild, stable hypogammaglobulinaemia (serum γ-globulin at 75% of lower limit of normal) had been diagnosed in 1978. He had remained in good health and did not receive immunoglobulin until 1988 when he was given a single infusion of γ-globulin before a total gastrectomy for a superficial adenocarcinoma of the stomach without local lymphatic spread. He suffered no postoperative complications and remained well until early 1993 when he started experiencing frequent lower respiratory tract infections requiring treatment with multiple courses of antibiotics. In July 1993 the patient developed persistent pyrexia which did not respond to broad spectrum antibiotics.

Apart from moderate splenomegaly, physical examination was normal. The patient’s haemoglobin concentration was 100 g/l, and white cell count 3.4 x 10^9/l (neutrophils 69%, lymphocytes 17%, monocytes 9%, myelocytes 3%, eosinophils 1%, basophils 1%) with a normal platelet count. The percentage of B lymphocytes (CD19+) was within normal limits and the T_4/T_8 ratio was also normal at 1.6. The erythrocyte sedimentation rate was 44 mm/hour. His serum γ-globulin was 45% of the lower limit of normal: IgG 28 g/l (normal range 6-18), IgM 0.25 g/l (0.5-3.5) and IgA 0.18 g/l (1.4-6). Microbiological, serological, endoscopic, and radiological evaluation did not reveal the cause of the patient’s pyrexia. Computed tomography confirmed the presence of an enlarged spleen with a vertical span of 16 cm. A bone marrow aspirate showed iron deficiency and slightly increased numbers of megakaryocytes but was otherwise unremarkable. A trephine bone marrow biopsy specimen of the iliac crest showed extensive infiltration of the marrow by Hodgkin’s disease with a diffuse pattern of involvement. The neoplastic infiltrate was polycellular with numerous Reed-Sternberg (RS) cells and variants, many small and medium-sized lymphocytes, benign histiocytes, few plasma cells, and neutrophils (figure, panel A). Immunophenotyping on paraffin wax sections showed that the RS cells and variants were CD15+ (figure, panel B), CD30+, CD45-, CD45RO-, CD3- and CD20 associated (L-26)-; the bystander lymphocytes were predominantly of T cell origin (CD45+, CD45RO+, CD3+, CD20 associated (L-26)-) and only a small number were B lymphocytes (CD45+, CD20 associated (L-26)+, CD3-, CD45RO-). There was significant suppression of normal haemopoiesis.

Anaemia was relieved after transfusion of packed red cells through a leucocyte filter and chemotherapy was initiated with a modified EBVD (etoposide, bleomycin, vinblastine, dacarbazine, and prednisolone) regimen. Intravenous infusions of γ-globulin (200 mg/kg)
A paraffin wax section of a bone marrow biopsy specimen stained with haematoxylin and eosin. RS cells and variants can be seen against a polyscellular background.

(B) Paraffin wax bone marrow section stained immunohistochemically with Leu-M1 (anti-CD15) using the avidin-biotin peroxidase complex method following pretreatment in a microwave oven to enhance antigen retrieval. RS cells and their variants are strongly positive.

were given every two weeks. Chemotherapy was switched to MOPP (mustine, vincristine, procarbazine, and prednisolone) following an episode of unexplained liver dysfunction which occurred after the first cycle of the EBVD regimen. The patient received three cycles of the MOPP regimen. This was followed by five cycles of HOPE-Bleo without prednisolone (doxorubicin, vincristine, bleomycin, and etoposide). Episodes of pyrexia and abdominal pain coinciding with postchemotherapy leukocyte nadirs (<0.5 x 10^9/l) despite appropriate dose reductions of myelotoxic drugs and support with G-CSF necessitated hospital admission on each of the first five chemotherapy cycles. These episodes were associated with endoscopically confirmed erosive mucositis, which was unusually severe given the doses of cytotoxic drugs used. No pathogens were isolated at any time but pyrexia always seemed to respond to broad spectrum antibacterials. The patient was admitted to hospital with fever and abdominal pain on day 14 of the first MOPP cycle. Biopsy of an ulcerated area in the upper rectum revealed a malignant lymphocytic infiltrate with histology compatible with, but not diagnostic of, Hodgkin's disease. In the same biopsy specimen there were cellular inclusions suggestive of cytomegalovirus (CMV) infection. Polymerase chain reaction (PCR) examination of the colonic mucosa was positive for CMV. No specific antiviral treatment was given at that point in view of the absence of active colitis. Following the third MOPP cycle, the patient complained of blurred vision in the right eye and fundoscopic examination revealed florid retinitis with appearances suggestive of herpetic or CMV aetiology. PCR of aqueous humour was negative for herpes simplex, zoster, CMV, and Epstein–Barr viruses. Treatment with standard doses of intravenous foscarnet through a Hickman catheter was administered for five weeks. The frequency of the ζ-globulin infusions was doubled during this time. There was a dramatic response with complete resolution of retinal changes and restoration of normal visual acuity. Foscarnet treatment was complicated by severe hypokalaemia and hypocalcaemia requiring intensive potassium and calcium replacement based on daily biochemical monitoring.

Despite the numerous treatment-related problems there was a steady improvement in the overall condition of the patient. He became afebrile shortly after the onset of chemotherapy. Repeat sigmoidoscopy and biopsy were normal after the fourth chemotherapy cycle and his peripheral blood counts gradually returned to normal with correction of the leucopenia and anaemia. Bilateral iliac crest bone marrow biopsy specimens taken after marrow regeneration following the sixth and ninth chemotherapy cycle showed no evidence of Hodgkin's disease. A repeat computed tomography scan of the abdomen at the same time confirmed that splenomegaly had resolved. The patient is in excellent clinical condition six months after completion of chemotherapy, his only treatment consisting of monthly ζ-globulin infusions (400 mg/kg).

Discussion

The increased incidence (varying from 1.4 to 8%) of lymphoma in patients with common variable immunodeficiency is well documented in both prospective and retrospective studies with an apparently high frequency of undifferentiated and T cell tumours. The diagnosis of Hodgkin's disease was made in one patient with common variable immunodeficiency in the Minnesota Immunodeficiency/Cancer Registry and a second case has been mentioned in the recent survey by Hermaszewski and Webster, although the authors comment that there was no evidence that the hypogammaglobulinaemia had preceded.
the presentation of Hodgkin's disease. There are certain points in our report that deserve comment; the first concerns the difficulties in diagnosing extranodal Hodgkin's disease. The presence of RS cells, even when they are CD15+, is not diagnostic of Hodgkin's disease as CD15+ RS-like cells have been described in T cell non-Hodgkin's lymphoma.\textsuperscript{10} RS-like cells (CD15–) were present in the bone marrow of a patient with common variable immunodeficiency who developed a peripheral T cell non-Hodgkin's lymphoma.\textsuperscript{7} In the case reported here, it was the combination of typical histopathology and immunophenotype that was diagnostic of Hodgkin's disease in the bone marrow. The nature of the lymphoproliferative infiltrate found on rectal biopsy was less clear but it should be noted that, although colonic localisation of Hodgkin's disease is considered extremely unusual in previously immunocompetent patients, this might not be the case in immunodeficient subjects.

Although the response of this patient to treatment was gratifying, there were many problems caused by the chemotherapy. The unusual severity of mucositis and gastrointestinal symptoms might be related to compromised mucosal defences because of his severe IgA deficiency. The rapidly advancing viral retinitis—uncommon in most immunocompetent patients undergoing chemotherapy—was compatible with the tendency of latent viruses to reactivate in patients with common variable immunodeficiency. Decliniling the dose of γ-globulin during treatment with foscarnet may have played a role in the spectacular resolution of fundal changes.

In conclusion, this case report of Hodgkin's disease complicating common variable immunodeficiency illustrates that aggressive combination chemotherapy can be successful even in stage IVB disease, although unusual clinicopathological presentations and a broad spectrum of treatment related complications should be anticipated.

We thank Drs G Daikos and N Markomichelakis for help with the clinical management of this patient and Drs M Daemenacou and C Lilogiou for performing histopathology studies and PCR analyses, respectively.

Immunohistochemical analysis of T cell proliferation in normal tonsil and B cell lymphoma

J Wang, P G Isaacson, J Spencer

Abstract

A double immunohistochemical technique, incorporating MIBI and CD3, was used to identify proliferating T cells in paraffin wax sections of normal tonsil and B cell lymphomas. The number of double stained T cells as a percentage of the total T cells was then determined. In normal tonsil and follicular lymphoma the follicle centre and T cell zones were counted independently. In normal tonsil very few T cells in the follicle centre expressed MIBI. Proliferating T cells were concentrated in the T cell zones. The same pattern was observed in follicular lymphoma. In contrast, the percentage of T cells expressing MIBI was higher in mucosa associated lymphoid tissue type lymphomas and lymphoblastic lymphomas, suggesting that T cell activation occurs in these tumours. The highest percentage of MIBI positive T cells was observed in high grade lymphoma. This suggests that transformation to high grade lymphoma is associated with an increase in T cell activation.
