In situ detection of lipid peroxidation in chronic hepatitis C: correlation with pathological features

Abstract

Aims—To assess the occurrence of lipid peroxidation in chronic hepatitis C and to evaluate its relation to pathological features and liver iron concentrations.

Methods—Liver biopsy samples of 43 patients with untreated chronic hepatitis C were studied by immunohistochemistry using specific antibodies directed against two major aldehyde metabolites of lipid peroxidation, malondialdehyde (MDA), and 4-hydroxynonenal (HNE).

Results—MDA and HNE adducts (aldehydes covalently linked to another molecule) were detected in the liver samples in 77% and 30% of cases, respectively. MDA adducts were detected both in the extracellular matrix and sinusoidal cells localised in areas of periportal and lobular necrosis. HNE adducts appeared in the cytoplasm of only a few hepatocytes. Comparison of the semiquantitative assessment of adducts (MDA and HNE indexes) with the grading and the staging of chronic hepatitis showed that the MDA index was correlated with fibrosis score (p < 0.001) and the grade of activity (p < 0.01). There was also a tendency to correlation with liver iron concentration (p = 0.09). No correlation was observed between the HNE index and pathological features or liver iron concentration.

Conclusion—Lipid peroxidation products are detectable in the liver of chronic hepatitis C patients. The presence of MDA adducts in areas of active fibrogenesis and the correlation between the MDA index and fibrosis score suggest a role for lipid peroxidation in liver fibrosis.

Keywords: lipid peroxidation; chronic hepatitis C; immunohistochemistry

A major and frequent complication of chronic hepatitis C virus infection is the development of liver fibrosis leading to cirrhosis in about 20% of cases. The pathogenesis of hepatitis C virus-induced liver damage and liver fibrogenesis is unclear. Based on data obtained in chronic hepatitis B virus infection, it has been proposed that fibrosis could be the result of necroinflammatory lesions (activity), but the precise mechanisms linking hepatitis C virus infection, chronic inflammation, and fibrosis have not been determined. Among factors involved in fibrogenesis, cytokines, growth factors, and iron overload have been considered. Furthermore, several recent studies have suggested that lipid peroxidation might play a role in the fibrogenesis observed in some chronic liver diseases. It was therefore proposed that there may be a link between tissue injury and liver fibrosis by modulating collagen gene expression.

Lipid peroxidation is caused by free radicals leading to oxidative destruction of polyunsaturated fatty acids constitutive of cellular membranes. Their destruction leads to the production of toxic and reactive aldehyde metabolites such as malondialdehyde (MDA) and 4-hydroxynonenal (HNE). These highly cytotoxic metabolites, produced in relatively large amounts, can diffuse from their site of origin to attack distant targets and form covalent links with various molecules (adducts). Therefore, recognition of lipid peroxidation is of interest, as the deleterious effects of this process, including fibrogenesis, might be prevented by administration of scavenging systems or antioxidants.

Most previous studies investigating lipid peroxidation dealt with blood and tissue extracts by indirect quantitative methods; the thiobarbituric acid (TBA) test has been the most commonly applied. Using this procedure, an increase in MDA was observed in serum and liver of patients with chronic hepatitis C. Recently, specific antibodies against MDA and HNE adducts have been raised. These antibodies can be used to detect in situ the presence of these lipid peroxidation-derived adducts and to specify their cellular localisation.

The aim of this study was to investigate the role of lipid peroxidation in chronic hepatitis C and its relation with liver fibrosis. To assess the occurrence of lipid peroxidation, MDA and HNE adducts were detected on liver biopsies with an immunohistochemical procedure. The presence of these adducts was then correlated with the grade of activity and the stage of fibrosis assessed on the same biopsy. As iron overload has been reported in chronic hepatitis C, and as this molecule is a cofactor in lipid peroxidation, the presence of these aldehyde adducts was also correlated with liver iron concentration.

Patients and methods

STUDY GROUP
Forty three patients were studied. All patients were positive for antibody to hepatitis C virus by second generation tests. Serum viral load
was quantified by branched DNA (second generation bDNA Ampex Chiron, Chiron, Emeryville, California, USA) in 33 patients. Genotype determination was carried out by a competitive oligonucleotide priming–polymerase chain reaction procedure in 32 patients. All patients were hepatitis B virus negative and had not received any antiviral therapy at least six months before biopsy. Alcohol consumption was recorded in 41 of the 43 patients. Five histologically normal livers in patients without hepatitis C virus infection were used as controls. These were obtained from surgical resections performed for tumours in an otherwise normal liver.

LIVER BIOPSIES
Liver biopsy specimens were obtained for each patient using a percutaneous procedure. The liver sample was fixed, paraffin wax embedded, and processed for histological study according to standard procedures (haematoxylin and eosin, Perl's blue, Masson's trichrome). Serial sections were performed for the immunohistochemical study. When enough tissue was available (n=21), the liver iron concentration was determined.

Liver biopsies were examined by two pathologists (VP, PB) in a simultaneous reading. They were blind to the results of lipid peroxidation immunostaining. For each liver biopsy, the semiquantitative assessment of grade of activity and stage of fibrosis according to Metavir was recorded. The activity of chronic hepatitis was graded as follows: A0, no histological activity; A1, minimal activity; A2, moderate activity; A3, severe activity. The degree of disease activity was defined by the integrated assessment of the major necroinflammatory lesions according to an algorithm previously described. This grading is based on the semiquantitative assessment of piecemeal necrosis (0, absent; 1, mild; 2, moderate; 3, severe) and lobular necrosis (0, absent or mild; 1, moderate; 2, severe). Fibrosis was defined as follows: F0, no fibrosis; F1, portal fibrosis without septa; F2, portal fibrosis with rare septa; F3, numerous septa without cirrhosis; F4, cirrhosis.

IMMUNOHISTOCHEMICAL STUDY
Antibodies
Polyvalent monospecific antisera were generated by immunising Watanabe heritable hyperlipidaemic rabbits with homologous low density lipoprotein (LDL) which had been modified in vitro with either HNE or MDA. LDL (1.020–1.057 g/ml) was prepared from 10 ml rabbit blood plasma by sequential ultracentrifugation by using 2.7 mM EDTA, 2 mM benzamidine, 1 μM D-phenylalanyl-L-propyl-L-arginine chloromethyl ketone, 0.01% aprotinin, 50 μg/ml chloramphenicol, and 100 μg/ml gentamicin to counteract proteolysis. LDL was dialysed against phosphate buffered saline (PBS) containing 0.1 mM EDTA, 1 mM phenylmethylsulphonyl fluoride, and antibiotics. HNE was generated by acid hydrolysis of hydroxynonenal diethylacetal for one hour at 37°C. Ten milligrams of purified LDL were incubated with 20 mM (final concentration) NaN3, 20 mM EDTA, and 4 mM HNE in PBS, pH 8.5 for 24 hours at room temperature. After formation of HNE-LDL adducts, excess reagents were removed by extensive dialysis against PBS. The extent of conjugation of lysozyme residues was 34%, as estimated by the trinitrobenzene sulphonic acid assay.

MDA was generated by acid hydrolysis of MDA-bis-dimethylacetal (Serva, Heidelberg, Germany). MDA-bis-dimethylacetal (880 μl) was incubated with 120 μl of 4N HCl and 4 ml distilled water for 30 minutes at 37°C and titrated to pH 7.6. Ten milligrams of purified LDL in PBS were incubated with 300 μl of 0.5 M MDA pH 8.5 for three hours at room temperature. After formation of MDA-LDL adducts excess reagents were removed by extensive dialysis against PBS buffer. The extent of conjugation of lysozyme residues was 78%, as estimated by the trinitrobenzene sulphonic acid assay.

Primary immunisation of Watanabe heritable hyperlipidaemic rabbits consisted of intradermal injections of 200 μg of antigen in 50 μl PBS suspended with 500 μl Freund's complete adjuvant. For booster injections, 150 μg of antigen were administered in Freund's incomplete adjuvant subcutaneously after two and four weeks. Six weeks after the first immunisation, blood serum was collected. The specificity of antibody was tested by Western blotting using HNE or MDA modified and unmodified proteins. The antibodies were specific for HNE or MDA modified epitopes (adducts).

Immunohistochemical procedure
The immunohistochemical procedure was performed on serial paraffin wax embedded sections using an automated immunostainer (Techmate 500, Dako, Carpenteria, California, USA) with the avidine-biotin-peroxidase method. For immunohistochemical detection of MDA modified epitopes, slides were pronase treated (0.01% in Tris NaCl, 25 minutes) before immunostaining. All primary antibodies were used at a 1:100 dilution.

Localisation and intensity of staining were assessed by the two pathologists in a simultaneous reading, blind to the results of grading and staging. The intensity of the staining (MDA or HNE index) was graded from 0 to 3: 0, no staining; 1, mild (punctuated labelling); 2, moderate (dense labelling in few cells or in few extracellular foci); 3, strong (dense and homogenous labelling in many cells or diffuse extracellular staining). This evaluation concerned the mean intensity of the signal on the whole slide. A global lipid peroxidation index was defined by adding the values of MDA and HNE indexes.

Negative controls were normal sheep serum or PBS instead of primary antibodies. Positive controls for lipid peroxidation detection were fixed, paraffin wax embedded rat liver samples from acute hepatitis induced by CCI4. These liver samples were removed 48 hours after an intraperitoneal injection of 100 μl/100 g body weight of CCI4, in male Wistar rats. In this
Lipid peroxidation in chronic hepatitis C

model, substantial necrosis of centrilobular areas was present 48 hours after CCl₄ injection, and it has been shown previously that lipid peroxidation is the major factor responsible for liver necrosis.²⁵

LIVER IRON CONCENTRATION

Liver iron concentration was measured in deparaffinised liver biopsies from 21 patients using the colorimetric assay of Barry and Sherlock.²⁶ Results were expressed in μmol/g of dry weight (dry weight > 0.60 mg for correct chemical iron determination). The normal range (1.2–19.5) was determined in 147 patients with chronic hepatitis C without iron overload using Perl’s staining method.

STATISTICAL ANALYSIS

Quantitative data are presented as mean (SD). Correlations between data were performed using Spearman and Pearson’s tests.

Results

STUDY GROUP

The study group consisted of 17 women and 26 men, mean age 48 years (range 28–74); 29 patients denied any alcohol consumption. Eleven patients were genotype 1b, five were genotype 1a, three were genotype 2a, seven were genotype 3a, four were genotype 4, two were genotype 1a+1b, and one could not be determined. Twenty nine of the 33 patients were hepatitis C virus RNA positive.

Metavir fibrosis grading was as follows: F0, one patient; F1, 18 patients; F2, 14 patients; F3, eight patients; F4, two patients. Six patients had no activity (A0), 15 had mild activity (A1), 11 had moderate activity (A2), and 11 had severe activity (A3).

The mean liver iron concentration determined in 21 patients was 15.1 (14.5) μmol/g (range 4–71).

IMMUNOHISTOCHEMICAL STUDY

In rat liver samples with CCl₄ induced damage, immunohistochemical study detected strong staining in areas of centrilobular necrosis both with anti-HNE and anti-MDA antibodies (data not shown). No staining was observed in portal tracts and perportal areas. In control experiments, where non-immune serum was used instead of anti-antibody, no staining was observed.

MDA or HNE adducts or both were detected immunohistochemically in 35 of 43 patients (81%). MDA adducts were detected in 33 of the 43 patients (77%). Staining was graded mild in 23 cases, moderate in nine cases, and strong in one case. Immunostaining was observed both in the extracellular matrix and sinusoidal cells. When staining was mild, it was restricted to the periportal areas (fig 1A). In cases of moderate or strong staining, a more diffuse portal labelling was observed, displaying a thin extracellular network (fig 1B). In these cases, patches of lobular staining were also present, localised in the sinusoidal cells in contact with lobular necrosis foci (fig 1C). No staining was observed in hepatocytes.

HNE adducts were detected in 13 of the 43 cases (30%). Ten of the 13 cases (77%) that displayed HNE adducts also showed MDA adducts. The staining was mild in 12 cases and moderate in one case. It was mainly intracellular and appeared in the form of small and large granules or vesicles in the cytoplasm of hepatocytes (fig 1D). No specific topographical distribution of labelling was observed and immunostaining was not co-localised with lobular or perportal necrosis.

The five histologically normal livers of control patients showed no labelling with anti-HNE antibody. Mild extracellular staining was observed in portal tracts with anti-MDA antibody.

CORRELATION BETWEEN LIPID PEROXIDATION AND BIOLOGICAL AND HISTOLOGICAL DATA

There was a significant correlation between the presence and the intensity of MDA adducts in the liver and both the grade of activity (p < 0.01) and the stage of fibrosis (p < 0.001). No correlation was observed between the HNE index and the grade of activity or the stage of fibrosis. The lipid peroxidation index was significantly correlated only with the stage of fibrosis (p < 0.01). The values of MDA, HNE, and lipid peroxidation indexes according to the grade of activity or the stage of fibrosis are reported in table 1.

MDA and HNE indexes were not significantly different in the group of patients with genotype 1b versus patients with other genotypes (MDA 0.92 (0.9) v 1.15 (0.56); HNE 0.23 (0.57) v 0.37 (0.49)). There was no correlation between MDA, HNE, or lipid peroxidation indexes and age or sex of the patients. Although lipid peroxidation, MDA, and HNE indexes were higher in alcohol consumers than in abstinent patients, these differences were not statistically significant (lipid peroxidation 1.75 (1.29) v 1.14 (0.88); MDA 1.25 (0.87) v 0.90 (0.67); HNE 0.50 (0.67) v 0.28 (0.45)).

Although not significant, there was a tendency to correlation between MDA index and liver iron concentration (p = 0.09). The liver iron concentration was 10.6 (3.2) μmol/g in the 14 patients with an MDA index of 0 or 1, and 17.4 (17.5) μmol/g in the seven patients with an MDA index of 2. There was no correlation between HNE index and liver iron concentration (14.6 (7.6) μmol/g in patients with an HNE index of 0 compared with 15.9 (22.4) μmol/g in patients with an HNE index > 0). No correlation was observed between lipid peroxidation index and liver iron concentration (14.2 (8.9) μmol/g in patients with a lipid peroxidation index of 0 or 1 compared with 16.1 (19.5) μmol/g in patients with a lipid peroxidation index > 1). Furthermore, liver iron concentration was correlated neither with the grade of activity nor the stage of fibrosis.

Discussion

Lipid peroxidation, a free radical induced mechanism, is implicated in the pathogenesis of several acute and chronic human disorders, including liver pathology.²⁷ The deleterious consequences of this mechanism are related in
Figure 1  Immunohistochemical detection of malondialdehyde (MDA) and 4-hydroxynonenal (HNE) in chronic hepatitis C. (A) Immunostaining of MDA adducts in chronic hepatitis C with mild activity (A1) and portal fibrosis (F1). A moderate MDA adduct immunostaining (grade 2) is observed in the perportal extracellular matrix (arrow). The centre of the portal tract is not labelled (magnification x25). (B) Immunostaining of MDA adducts in chronic hepatitis C with severe activity (A3). A strong MDA adduct immunostaining (grade 3) is detected in perportal areas both in the extracellular matrix and in sinusoidal cells (arrow) (magnification x100). (C) Immunostaining of MDA adducts in chronic hepatitis C with lobular necrosis. MDA adducts are observed in sinusoidal cells located in an area of lobular necrosis (mild staining, grade 1) (magnification x200). (D) Immunostaining of HNE adducts in chronic hepatitis C. A mild intracellular HNE adduct immunostaining (grade 1) is detected in the cytoplasm of a few hepatocytes in the form of either small granules close to steatosis vacuoles or intracytoplasmic vesicles (magnification x400).

part to the formation of aldehyde products such as MDA and HNE that bind to various molecules, impairing their functions.14

We investigated the presence of MDA and HNE adducts in liver samples from patients with chronic hepatitis C virus infection by an immunohistochemical procedure. Using this technique, we detected at least one marker of
lipid peroxidation in 81% of patients infected by hepatitis C virus. These results are concordant with previous studies performed on blood or tissue extracts, and suggest that lipid peroxidation occurs in chronic hepatitis C. Using immunohistochemistry, we were also able to elucidate the tissue structure of these aldehyde products in relation to pathological features.

This procedure revealed that MDA adducts are the major detectable aldehyde adducts in the liver, and the intensity of staining is correlated with the severity of chronic hepatitis. Although MDA and HNE are both products of lipid peroxidation, we observed that, for a given case, the intensity and localisation of MDA and HNE adducts were different. It is of note that production of lipid peroxidation byproducts does not imply their in situ immunohistochemical detection. In fact, we used antibodies that detect only MDA or HNE adducts but not free HNE and MDA. In order to be detected, these products have to be immobilised onto the tissue by binding to intracellular or extracellular molecules, a mechanism which differs according to the nature of the lipid peroxidation byproducts. MDA is a dialdehyde of short half life that reacts preferentially with amino groups of proteins, inducing the formation of intermolecular and intramolecular bridging. In contrast, HNE reacts with thiol groups and has a relatively long half life. The different immunostaining patterns observed between MDA and HNE reflect both their different biochemical properties and their different half lives.

The correlation between MDA index and the grade of activity of chronic hepatitis suggests that lipid peroxidation is involved in the pathogenesis of the necroinflammatory reaction. However, whether lipid peroxidation is the cause or the consequence of the liver damage remains to be elucidated. The presence of MDA adducts in occasional cases with no or mild activity may suggest a causative mechanism.

In vitro studies have shown that lipid peroxidation products stimulate collagen production by regulating collagen gene transcription in fibroblasts and hepatic stellate cells. In chronic hepatitis C virus infection, we observed a strong association between the MDA index or the lipid peroxidation index and the stage of fibrosis. Furthermore, MDA adducts were preferentially detected in sinusoidal cells in close contact with areas of active fibrogenesis.

These data suggest a causative relation between lipid peroxidation and liver fibrosis in patients with chronic hepatitis C virus infection.

In chronic hepatitis C, iron overload has been noted in some studies. Although slight, this overload has been evoked as a factor of resistance to interferon therapy. This is of interest as iron exerts its cytotoxic effects through enhanced formation of free radicals and lipid peroxidation stimulation. Although we observed a slight increase in liver iron concentration in our patients, a tendency to correlation was noted between liver iron concentration and the MDA index. If these results are confirmed in a larger samples of patients, it could be postulated that enhanced lipid peroxidation detected in chronic hepatitis C is linked in part to iron overload.

In conclusion, this study shows that lipid peroxidation products can be detected in liver biopsies of patients with chronic hepatitis C virus infection. There is experimental evidence showing that lipid peroxidation can be prevented by administration of scavengers of free radicals or antioxidants. It has been shown that lipid peroxidation products can stimulate fibrogenesis by inducing collagen gene expression thus, detection and prevention of lipid peroxidation could be of major interest in preventing fibrosis and cirrhosis in this disease.

This study was supported by a grant from the Association pour la Recherche contre le Cancer and from the Deutsche Forschungs Gemeinschaft. Hydroxynonenal diethylacetal was kindly provided by H Esterbauer and G Ware, University of Graz, Austria.
