Biochemical assessment of pancreatic disease in human immunodeficiency virus infected men

M R Hancock, N A Smith, D A Hawkins, B Gazzard, S G Ball

Abstract

Aim—To determine the usefulness of measuring amylase activity as an indicator of pancreatic disease in human immuno-deficiency virus (HIV) positive patients.

Methods—A prospective study of 129 ambulant HIV positive males. Total amylase, pancreatic amylase, and lipase activities were assayed using commercial test kits on an automated analyser. Samples with raised amylase were examined for the presence of macroamylasaemia using cellulose acetate electrophoresis.

Results—Thirty six (28%) of the subjects had raised total amylase activities compared with healthy, age matched blood donors. However, almost half of these were because of an increase of the salivary fraction. Four subjects were found to have macroamylasaemia. Pancreatic amylase and lipase assays, more specific indicators of pancreatic disease, produced significantly fewer abnormal results. There was no association between abdominal symptoms and elevated enzyme levels.

Conclusions—Total amylase is a poor indicator of pancreatic disease in HIV infected outpatients. Specific assays for pancreatic amylase offer advantages over the traditional total amylase assay. The lipase assay produced the least number of abnormal results and its use could improve the biochemical identification of patients with possible pancreatic disease and allow a more selective investigation of these cases.

Keywords: amylase; lipase; human immunodeficiency virus

A high incidence of pancreatic involvement has been observed postmortem in human immunodeficiency virus (HIV) infected patients. In a review of a previously reported series, evidence of pancreatic disease was seen in 254 of 749 cases where the pancreas was examined histologically.

Possible causes of pancreatic disease include opportunistic infections, Kaposi’s sarcoma, lymphoma, and the use of drugs such as pentamidine and didanosine for the treatment of HIV disease. Monitoring HIV infected patients for early signs of pancreatic involvement, particularly where drugs associated with pancreatic toxicity are being administered, is desirable.

The use of simple biochemical tests to monitor for pancreatic involvement are preferable to the use of more invasive or expensive tests such as endoscopic retrograde cholangiopancreatography and fast contrast enhanced computed tomography. Traditionally, amylase is used as the biochemical marker of pancreatitis; however, the availability of computed tomography has shown that up to 19% of patients with acute pancreatitis have serum amylase within the reference range and it is well recognised that amylase is raised in a variety of non-pancreatic diseases.

The reported incidence of hyperamylasaemia in HIV infected individuals depends on the population selected, varying from hyperamylasaemia without any other evidence of pancreatitis in 8% of patients being enrolled in a treatment study to 63% of patients on high dose didanosine. In one retrospective study of AIDS patients, hyperamylasaemia was present in 54% of those in whom amylase was measured; however, this was attributed to salivary amylase in a third of the cases. Pancreatitis was diagnosed in 31% of patients, although the disease tended to be mild.

One reason for concern is that a number of the drugs used in HIV related treatment are recognised as potential causes of pancreatitis. In particular, treatment with pentamidine and didanosine and, less commonly, zalcitabine and trimethoprim-sulphamethoxazole are associated with pancreatitis.

In a study of children receiving didanosine, asymptomatic hyperamylasaemia occurred in 37% of patients. Investigation of some of these patients revealed salivary macroamylasaemia. Macroamylasaemia appears to occur relatively frequently in HIV infected patients, it has been suggested that the increase in immunoglobulin associated with HIV infection may predispose to macroamylase formation.

Materials and methods

SERUM SAMPLES

Serum samples and brief clinical details were obtained from 129 consecutive HIV positive male patients attending outpatient clinics. Patients on clinical trials involving placebo controlled didanosine were excluded unless they were on open label drug. Patients were aged between 23 and 61 years (mean 35). One had a previous history of pancreatitis. For our reference population we used 52 male blood donors aged under 50 years.

REAGENTS

Samples were assayed on a Hitachi 911 autoanalyser (Boehringer Mannheim GmbH,
Mannheim, Germany) using the following reagents: \(\alpha\) amylase EPS test (Boehringer Mannheim) for the measurement of total amylase. This uses a protected para nitrophenol substrate. Pancreatic \(\alpha\) amylase EPS test (Boehringer Mannheim) for the measurement of pancreatic amylase after immunoinhibition of salivary amylase. Lipase-PS test (Sigma Diagnostics, St Louis, Missouri, USA) for the measurement of lipase using 1,2-diglyceride as a substrate in the presence of colipase and deoxycholate as activators. Macroamylasaemia was investigated using cellulose acetate electrophoresis.\(^10\)

**Results**

Reference ranges were established for the assays (see table 1).

No patient was thought to have clinical pancreatitis but on direct questioning 43 patients (33%) admitted to some degree of abdominal pain. There was no correlation between the presence or degree of abdominal pain and any of the parameters measured. One patient had a past history of pancreatitis but had no clinical or biochemical evidence of pancreatitis on this occasion.

Biochemical evidence suggestive of pancreatic disease was defined as the combined elevations of both pancreatic amylase and lipase. Nine such patients were identified (table 2).

The total amylase assay revealed hyperamylasaemia in 36 of the 129 patients (28%). All patients with a total amylase activity above 100 IU/l were examined for the presence of macroamylasaemia. Four cases of macroamylasaemia were demonstrated and in two of these the amylase was of the pancreatic type.

Excluding the patients with macroamylasaemia, 13 hyperamylasaemic patients were found to have a raised salivary fraction with a normal pancreatic specific amylase. Overall, 35% of patients complained of dry mouth but there was no association between this and abnormal salivary amylase concentrations.

Both the pancreatic amylase and lipase assays produced significantly less abnormal results. Twenty seven patients (21%) had raised pancreatic amylase, including two patients with macroamylasaemia and six patients whose total amylase was not raised. Only 15 patients (12%) had raised lipase levels (fig 1).

We compared the nine patients who had biochemical evidence suggestive of pancreatic disease with the 96 (74%) who had normal pancreatic amylase and lipase (including 15 with raised total amylase of salivary origin). There was no significant difference in age or the presence of abdominal pain between the two groups. Patients with raised pancreatic amylase and lipase had a significantly lower CD4 count (Mann-Whitney \(p = 0.036\)) and alcohol intake (Mann-Whitney \(p = 0.019\) (table 3). There were no statistically significant associations between drug therapy and hyperamylasaemia.

**Discussion**

Despite reports indicating that the pancreas is affected frequently by HIV infection, assessment of pancreatic involvement is hampered by

Table 1: Enzyme activities in 52 male blood donors

Table 2: Findings in nine patients with biochemical evidence of pancreatic disease

Table 3: Differences between patients with and without biochemical evidence of pancreatic disease
Lipase activity was raised in 15 of our patients and only in six was this not accompanied by a raised pancreatic amylase.

It is our view that the assay of plasma lipase should be the first line test in the investigation of pancreatic function in HIV infection where there is no clinical evidence of acute pancreatitis. This strategy would be no more expensive than measuring total amylase and would identify a smaller cohort of individuals who might benefit from more rigorous assessment of pancreatic status.

CONCLUSIONS

It appears that the frequency with which total amylase is raised makes it a poor indicator of pancreatic disease in HIV infected outpatients. The more specific assay for pancreatic amylase improves diagnostic capability but renal disease and macroamylasemia may still produce misleading results. The availability of improved lipase assays may reduce the number of patients identified as having possible pancreatic disease and allow more selective investigation of these cases.
