Metastasis of solid tumours in bone marrow: a study from Kashmir, India

Between 1935 and 2001, many studies have appeared in the literature from different parts of the world on bone marrow invasion by solid tumours. After lymphoma, the primary tumours that most frequently involve the bone marrow are malignancies of the prostate, breast, lungs, thyroid, kidney, and stomach.1 Metastatic deposits of malignant melanoma have also been described.2 In many instances, primary tumours remain clinically undetected and are identified only at necropsy.3

The value of bone marrow aspiration in the diagnosis of malignant neoplasms was confirmed when four of eight cases of malignant melanoma were found to harbour tumour deposits in the bone marrow.4 In a series of 57 patients with known carcinoma of the prostate, five had carcinoma cells in the bone marrow, with no other diagnostic evidence of skeletal system involvement.5 The usefulness of such a comparatively simple procedure is emphasised by studies of large series of patients with known malignancies,6 especially when the primary tumour is known to have a predilection for the skeletal system.

The patients in the abovementioned studies had known primary tumours and at present bone marrow aspiration/biopsy is routinely performed for staging of tumours, but the high incidence of metastatic deposits found in these bone marrows6 emphasises the practicability of routine bone marrow aspiration in patients with suspected malignancy or severe anaemia. It is difficult to determine from the literature the incidence of malignant cells in routine series of unselected bone marrow aspirates, so we investigated the usefulness of routine bone marrow examination for the diagnosis of malignancies.

A one year prospective study covering the year 2001 was conducted in the department of pathology, Government Medical College, Srinagar, Kashmir, India. The bone marrow smears were routinely stained by Leishman's stain and Perl's reaction. Periodic acid Schiff and Sudan black stain were used and when required. Of the 318 bone marrow samples studied during the year 2001, eight cases contained metastatic deposits. All of the patients in our present study had pallor (anaemia) as one of the main symptoms, and underwent bone marrow aspiration to determine which type of anaemia they were suffering from. In patients with metastatic deposits the normal haemopoietic cells of the bone marrow are replaced by tumour cells, resulting in myelolytic anaemia, and later on they are liable to develop myeloid metaplasia and myelofibrosis. In most of the cases, the bone marrow was difficult to aspirate, especially in cases of epithelial cell deposits, with mostly cancer cells obtained in a background of peripheral blood—a fact that has already been reported.3

After leukaemia, lymphoma most commonly involves the bone marrow and almost 10% of cases of lymphoma invade the bone marrow. In our present study, lymphoma (non-Hodgkin lymphoma) made up a quarter (two cases) of all the secondary tumours of the bone marrow, along with neuroblastoma (two cases)—a childhood tumour. Neuroblastoma, non-Hodgkin lymphoma, and acute lymphoblastic leukaemia pose a considerable amount of difficulty in diagnosis because all three are round cell tumours with a very similar morphological appearance. In acute lymphoblastic leukaemia, the peripheral blood film examination is of paramount importance because it shows the presence of lymphoblasts, which are larger than bone marrow smears tend to form rosettes and may show neural or neurofibillary differentiation. Non-Hodgkin lymphoma is thought of as a malignancy of old age, although it can be seen at any age; however, childhood lymphomas are mostly of high grade.

In most studies, the incidence of tumour deposits in the bone marrow varies from gastrointestinal tumours was low, but they made up a quarter of the cases presented here (two cases). This could be explained by the low number of cases in our study, together with the high incidence of gastrointestinal cancers, especially of the oesophagus and stomach, seen in Kashmir. Deposits from prostate and breast tumours (one case each) are known to have a predilection for skeletal metastasis.

Finally, several features worthy of comment are that the metastatic tumour cells are easily identified in the bone marrow smears because they look foreign within the native bone marrow cell population. These cells are usually identified in groups, even at low power examination, because they are larger than most of the bone marrow cells. Single cells are more difficult to recognise, although they never resemble the normal bone marrow cells. The primary site of the malignant deposits may be extremely difficult to determine on a morphological basis only, but their origin can sometimes be inferred from their morphological appearance, especially in mucous producing carcinoma, squamous carcinoma, some adenocarcinomas, and in many cases of metastatic neuroblastoma or melanoma.

Fatal water intoxication

Water intoxication can occur in a variety of different clinical settings but is generally not well recognised in the medical literature. The condition may go unrecognised at all stages when the patient may have symptoms of confusion, disorientation, nausea, and vomiting, but also changes in mental state and psychotic symptoms. Early detection is crucial to prevent severe neurological damage, which can lead to seizures, coma, and death.

The patient reported here was a 64 year old woman with a known history of mitral valve disease who was repeatedly admitted earlier with signs of dilutional hyponatraemia, especially of the oesophagus and stomach, seen in Kashmir. Deposits from prostate and breast tumours (one case each) are known to have a predilection for skeletal metastasis.

extracellular osmolality. Symptoms can become apparent when the serum sodium falls below 120 mmol/litre, but are usually associated with concentrations below 110 mmol/litre. Severe symptoms occur with very low serum concentrations of 90–105 mmol/litre. As the sodium concentration falls, the symptoms progress from confusion to drowsiness and eventually coma. However, the rate at which the sodium concentration falls is also an important factor, and the acute intake of large volumes of water over a short period of time, as occurred in this case, would have produced a rapid drop in serum sodium, which was fatal.

Postmortem serum samples are unsuitable for sodium measurement because concentrations decrease after death and there is considerable individual variation. However, vitreous sodium concentrations are stable in the early postmortem period, and the concentration in vitreous humour is similar to that found in normal serum. Studies have shown that abnormal vitreous humour sodium concentrations had corresponding antemortem biochemical investigations. Both clinicians and pathologists need to be aware of this condition, which may manifest itself as a psychotic illness and so go unrecognised in its early stages. Early detection is crucial to prevent fatal complications.
