CASE REPORT

Fatal renal failure as the first manifestation of sarcoidosis diagnosed on necropsy in a young man: a case report
A Awasthi, R Nada, P Malhotra, R Goel, K Joshi

Renal involvement as the first manifestation of sarcoidosis is rare and has never been reported in India. This report describes a 35 year old man who was admitted to the emergency department with a clinical diagnosis of acute on chronic renal failure, secondary to obstructive uropathy. Postmortem examination unexpectedly revealed disseminated sarcoidosis.

A 35 year old man presented to the emergency department with a one week history of oliguria and altered sensorium. There was no history of renal colic, haematuria, or dysuria and there were no respiratory complaints in the past. On examination, he had bilateral “wet” crackles suggestive of fluid overload and a biphasic pericardial rub. There was no lymphadenopathy or hepatosplenomegaly.

Investigations revealed severe dimorphic anaemia (haemoglobin, 44 g/litre), leucocytosis (total leucocyte count, 14.4 x 10^9/litre), and a raised erythrocyte sedimentation rate (82 mm first hour). Blood urea and serum creatinine were raised at 400 mg% and 9.7 mg%, respectively. Urine examination revealed 1+ albuminuria, pyuria (8–10 pus cells/high power field), and microhaematuria (8–10 red blood cells/high power field). The kidneys were normal in size (right, 9.7 cm; left, 9.9 cm) on ultrasonography. However, there was an indistinct corticomedullary differentiation, along with bilateral hydroureteronephrosis and left sided nephrolithiasis. Biochemical analysis revealed normal serum sodium (130 and 133 mg%, respectively) and potassium (3 and 5.2 mg%, respectively) values. Inorganic phosphate was raised (11.7 mg%), whereas serum calcium was low to normal (8.8 mg%). Liver function tests and total proteins (60 g/litre; albumin to globulin ratio of 1.0) were within normal limits. Arterial blood gases revealed metabolic acidosis and there was evidence of pulmonary oedema on chest x ray. Pus from a 2 x 1.5 cm sized perianal abscess grew Escherichia coli sensitive to amikacin. Blood and urine cultures were sterile. The patient was treated with intravenous cloxacillin and amikacin at renal modified doses. Eighteen cycles of peritoneal dialysis were carried out; however, he had an episode of ventricular fibrillation and died.

A complete necropsy was performed after informed consent from the relatives. Both kidneys were normal in size (left, 9.7 cm; right, 9.5 cm) with evidence of bilateral hydroureteronephrosis. There was a 3 cm diameter stone in the left renal pelvis and a 2 cm diameter stone in the lower part of the left ureter. Microscopic examination revealed pronounced nephrocalcinosis in the form of calcification of the basement membranes and tubular epithelium, along with the interstitium (fig 1). In addition, there were focal masses of calcification surrounded by polymorphs. Calcification of the smooth muscles and the intima of medium sized blood vessels and glomeruli (fig 1, inset) was also present. The lungs were subcrepitant and there were enlarged hilar lymph nodes (2.5 x 4 cm in diameter). On microscopy of the lungs, typical non-caseating epithelioid cell granulomas were seen (fig 2). Metastatic calcification was seen in the alveolar septae and blood vessels. The hilar lymph nodes showed diffuse paracortical sclerosis and the presence of fibroed granulomas in the cortex. Giant cells in these granulomas revealed asteroid bodies. The liver was normal on gross examination. However, microscopically there were stellate scars connecting portal tracts and central veins. Some of these scars were composed of healed epithelioid cell granulomas with giant cells containing asteroid bodies (fig 3). Similar lesions were seen in the spleen. There was no evidence of necrosis in the granulomas. Metastatic calcification was also present in the duramater, myocardium, and in the vessels of the gastrointestinal tract and brain.

Therefore, the final postmortem diagnosis was sarcoidosis involving the lung, hilar lymph nodes, liver, and spleen with renal involvement in the form of nephrocalcinosis, hydroureteronephrosis secondary to nephrolithiasis, and chronic interstitial nephritis. There was also evidence of widespread metastatic calcification in the duramater, myocardium, and the blood vessels of the gastrointestinal tract and brain.

DISCUSSION
Sarcoidosis, a disease that is increasingly being recognised in India, primarily involves the lungs and lymphatic system. Renal involvement is less frequent; the incidence in the West ranges from 7% to 22%, whereas two large
25(OH)2 vitamin D3 deficiency also interferes with calcium skeletal responsiveness to parathyroid hormone. The 1,25(OH)2 vitamin D3 production of 1,25(OH)2 vitamin D3 result in reduced renal failure, reduced excretion of phosphate and decreased calcium concentrations may be normalised as a result of secondary hyperparathyroidism of renal failure or widespread metastatic deposition of calcium.

The presence of normal serum calcium in a patient usually composed of calcium oxalate crystals, were the first manifestation of disease in 2.2% of their patients, although unlike our present case, none of the patients in that series presented with renal failure.7 In our case, in addition to the large left sided renal and ureteric calculi there was pronounced tubular, vascular, and focal glomerular calcification. The pathophysiological mechanisms responsible for renal failure in sarcoidosis include a direct effect of hypercalcaemia, dehydration, nephrocalcinosis, and tubulo-interstitial disease.1 Most of these factors probably contributed to the renal failure in our patient. In contrast to the cases of renal sarcoidosis reported by Ohashi and colleagues6 and Fernandez Giron et al.,8 where hypercalcaemia accompanied renal failure, the index case had normal calcium values at presentation. However, hypercalcaemia in the past probably contributed to the renal failure. This was evident from the widespread metastatic calcification including severe nephrocalcinosis seen at necropsy, which suggests the presence of at least moderate to severe hypercalcaemia in the past. In fact, the presence of metastatic calcification usually correlates with serum calcium concentration over 13 mg%.10 The low to normal serum calcium in our patient is also attributable to the presence of advanced renal failure. In renal failure, reduced excretion of phosphate and decreased production of 1, 25(OH)2 vitamin D3 result in reduced skeletal responsiveness to parathyroid hormone. The 1, 25(OH)2 vitamin D3 deficiency also interferes with calcium absorption from the gut, which is already impaired in uremia.

In conclusion, our case shows that renal failure resulting in death can rarely be the initial manifestation of sarcoidosis. The presence of normal serum calcium values in a patient with nephrocalcinosis, nephrocalcinosis, and advanced renal failure does not exclude sarcoidosis as a possible cause; calcium concentrations may be normalised as a result of secondary hyperparathyroidism of renal failure or widespread metastatic deposition of calcium.

ACKNOWLEDGEMENTS

We are grateful to Professor SK Jindal, Head of the Department of Pulmonary Medicine, PGIMER, Chandigarh for providing guidance and data on sarcoidosis in India during the preparation of this manuscript.
