Serous adenocarcinoma of the sigmoid mesentery arising in cystic endosalpingiosis

A McCoubrey, O Houghton, K McCallion, W G McCluggage

CASE REPORT

This case report describes a Mullerian serous adenocarcinoma arising within a multiloculated cyst lined by ciliated serous-type epithelium located in the sigmoid mesentery. Twenty years previously the patient underwent a hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. The ovaries contained bilateral serous cystadenofibromas, and multiple cysts lined by ciliated serous-type epithelium were present in the omentum. The resection specimen 20 years later contained a 14 cm multiloculated cyst located in the sigmoid mesentery. This was lined largely by benign ciliated serous-type epithelium but a focus of well differentiated serous adenocarcinoma projected into the lumen. Two further peritoneal cysts were present, both of which were lined by ciliated serous-type epithelium. There was a coincidental renal cell carcinoma. This is a unique case of multiple omental, peritoneal, and retroperitoneal cysts (classified as cystic endosalpingiosis), one of which developed a focus of serous adenocarcinoma. Although rarely serous adenocarcinomas, similar to those occurring within the ovary, arise in the retroperitoneum, this is the first reported occurrence in association with a pre-existing benign lesion.

Serous adenocarcinoma is the most common epithelial ovarian malignancy. Identical tumours arising as primary peritoneal lesions are well described, and are known as primary peritoneal serous carcinomas. However, primary serous adenocarcinoma of the retroperitoneum is very rare with, as far as we are aware, only four previously reported cases in the English language literature. We describe a case of a retroperitoneal serous adenocarcinoma arising in the sigmoid mesentery in a woman who had a hysterectomy, bilateral salpingo-oophorectomy, and omentectomy 20 years earlier. Bilateral ovarian serous cystadenofibromas were present and multiple cysts lined by ciliated serous-type epithelium, in keeping with cystic endosalpingiosis, were present in the omentum in the original specimen and in the peritoneum and sigmoid mesentery 20 years later. The large cyst in the sigmoid mesentery contained a focus of well differentiated serous adenocarcinoma projecting into the lumen. As far as we are aware, this is the first reported case of malignant transformation of cystic endosalpingiosis and the first documented example of a retroperitoneal serous adenocarcinoma arising within a pre-existing benign lesion.

“This is the first reported case of malignant transformation of cystic endosalpingiosis”

CASE REPORT

A 72 year old woman was being followed up for colitis and colonic polyps. At routine review, she was found to be anaemic and described weight loss of 12 kg. Abdominal examination was unremarkable but a digital rectal examination revealed a palpable mass anteriorly, which appeared to be extrinsic to the rectum.

Her past history included a total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy 20 years previously for a fibroid uterus and bilateral ovarian masses. Multiple small cysts were noted within the omentum at that time.

At this review, an ultrasound scan of the abdomen showed a 6 cm solid lesion in the lower pole of the right kidney. A large mass was present in the pelvis, which was indenting the bladder wall. A computed tomography scan of the abdomen and pelvis confirmed the presence of a large mainly cystic mass arising from the pelvis, with a solid component inferiorly. The presence of a mass within the right kidney was confirmed. The serum CA125 concentration was 72 units/ml.

A right nephrectomy and pelvic cystectomy were performed. At surgery, a 14 cm cystic mass was adherent to and indistinguishable from the sigmoid mesentery. The cyst was removed en bloc with rectum and sigmoid colon with primary anastomosis and defunctioning loop ileostomy. There were two further small 1–2 cm peritoneal cysts, one in the left lower quadrant and one in the right upper quadrant, which were removed.

PATHOLOGICAL FINDINGS

The slides of the original specimen were reviewed. This confirmed bilateral ovarian serous cystadenofibromas, measuring 15 cm and 8 cm in maximum dimension. These contained multiple cysts lined by benign ciliated serous-type epithelium set in a fibrous stroma (fig 1). In addition, multiple cysts—the largest measuring 1.5 cm in maximum dimension—were present in the omentum lined by ciliated serous-type epithelium. The uterus contained benign leiomyomas.

The second specimen consisted of a right nephrectomy together with a 30 cm length of sigmoid colon and rectum. A 6 cm tumour was located in the lower pole of the right kidney. A 14 cm multiloculated thick walled cystic mass was located in the mesentery of the sigmoid colon. A 4 cm solid white coloured nodule was present at one aspect projecting into the lumen of the cyst. Two thin walled cysts, measuring 2 and 1 cm in maximum dimension, were submitted separately.

Histology of the renal tumour showed a clear cell carcinoma, which invaded the renal vein (stage 3B). The cyst within the sigmoid mesentery was largely lined by a

Abbreviations: CK, cytokeratin
single layer of benign ciliated serous-type epithelial cells with surrounding fibrous tissue (fig 2). In areas, the epithelial lining was eroded and replaced by haemosiderin laden macrophages. Endometrial-type stroma was not present. The solid nodule was composed of a complex papillary and glandular arrangement of cuboidal cells with mild to moderate nuclear atypia, in keeping with a well differentiated serous adenocarcinoma (fig 3). This was confined within the lumen of the cyst with no invasion of the wall. Areas of transition could be seen between the benign ciliated lining and the well differentiated serous adenocarcinoma.

Immunohistochemically, the tumour cells were positive for cytokeratin 7 (CK7), Wilms tumour gene (WT1), the oestrogen receptor, and the progesterone receptor, but were negative for CK20. The two smaller cysts were lined by ciliated serous-type epithelial cells.

DISCUSSION
Primary retroperitoneal epithelial neoplasms are rare, occurring almost exclusively in women. They may be of serous or mucinous type and, similar to their ovarian counterparts, may be benign, borderline, or malignant. Serous adenocarcinomas in this area are exceptionally rare, with only four previously reported cases,3–6 one of which occurred in an 11 year old girl.6 Morphologically, these tumours are identical to ovarian serous adenocarcinomas, but are not attached to the ovary. This is the first report of a serous adenocarcinoma arising in this location within a pre-existing benign cystic lesion. There are several theories regarding the histogenesis of these neoplasms. They could arise from heterotopic ovarian tissue but ovarian remnants have not been found within the tumours. A more plausible explanation is an origin from the secondary Mullerian system, as described by Lauchlan.10

In our case, the adenocarcinoma arose within a benign cyst lined by ciliated serous-type epithelium. We prefer to classify this as cystic endosalpingiosis rather than a pre-existing benign extraovarian serous cystadenoma because multiple lesions were present in both specimens. Endosalpingiosis is defined as the presence of benign ciliated serous-type epithelium outside the ovary and fallopian tube, the most common locations being the peritoneum and omentum.11 12 Usually, endosalpingiosis is an incidental microscopic finding but rarely this may be cystic, forming a unilocular or multiloculated cystic mass, referred to as florid cystic endosalpingiosis.2–5 Endosalpingiosis is especially common in association with serous tumours of the ovary, probably representing a “field change” effect of the secondary Mullerian system.5 In our patient, bilateral ovarian serous cystadenofibromas were removed 20 years previously. At this time, several omental cysts lined by ciliated epithelium were present, in keeping with cystic endosalpingiosis. In addition, there were two further foci of peritoneal cystic endosalpingiosis in the second resection specimen separate from the large mass within the sigmoid mesentery.

“Optimal treatment for a serous adenocarcinoma arising in the retroperitoneum has not been established because of the rarity of these neoplasms”

We prefer to categorise the nodule projecting into the cyst lumen in the sigmoid mesentery as a well differentiated serous adenocarcinoma confined within the cyst, rather than a serous borderline tumour or an intraepithelial serous carcinoma. The overall architecture was not that of a serous borderline tumour but rather of a well differentiated serous adenocarcinoma. The term intraepithelial serous carcinoma, although used by some authors, is not in widespread use. The immunohistochemical features of the adenocarcinoma are entirely in keeping with a Mullerian neoplasm with positivity for CK7, the oestrogen receptor, and the progesterone receptor and negative CK20 staining. In addition, there was nuclear Wilms tumour gene (WT1) positivity, as is seen in

- We report a unique case of a serous adenocarcinoma arising in the sigmoid mesentery within pre-existing cystic endosalpingiosis.
- Although benign papillary proliferations have rarely been described in endosalpingiosis, this is the first report of malignant transformation of this benign condition.
- Malignant transformation occurred over a long time period—multiple foci of endosalpingiosis were present in a resection 20 years previously.

almost all primary ovarian and peritoneal serous carcinomas.13–15 This provides further evidence for a Mullerian, specifically a serous, phenotype.

Optimal treatment for a serous adenocarcinoma arising in the retroperitoneum has not been established because of the rarity of these neoplasms. Complete tumour resection is the mainstay of treatment. Adjuvant chemotherapy may be considered in patients with invasion of adjacent organs or in the presence of regional lymph node metastases. Combination chemotherapy should be based on regimens used for ovarian epithelial malignancies. In this case, ovarian-type chemotherapy was not administered because the carcinoma was small and well differentiated, and was confined within the lumen of a pre-existing cystic lesion. This is analogous to the situation with a small well differentiated serous adenocarcinoma within and confined to the ovary (stage 1A), where adjuvant chemotherapy would not be given. Moreover, in our present case a coincidental renal cell carcinoma was present, and the ultimate prognosis will probably depend on the renal tumour.

In summary, we report a unique case of a serous adenocarcinoma arising in the sigmoid mesentery within pre-existing cystic endosalpingiosis. Although benign papillary proliferations have rarely been described in endosalpingiosis,16 this is the first report of malignant transformation of this benign condition. Malignant transformation occurred over a long time period in that multiple foci of endosalpingiosis were present in the resection 20 years previously.
