BRAF and NRAS mutations are uncommon in melanomas arising in diverse internal organs

C W Wong, Y S Fan, T L Chan, A S W Chan, L C Ho, T K F Ma, the Cancer Genome Project, S T Yuen, S Y Leung

Background: Malignant melanoma arising from different body compartments may be associated with differing aetiological factors and clinical behaviour, and may manifest diverse molecular genetic profiles. Although many studies have focused on cutaneous melanoma, little is known of mucosal and other types of melanoma. In particular, malignant melanoma of soft parts is different from other melanomas in many respects, yet manifests a common melanocytic differentiation. Mutation of BRAF is now known to be common in cutaneous melanomas, and raises possible new therapeutic options of anti-RAF treatment for these patients. Few data are available for non-cutaneous melanomas.

Aims: To study the incidence of BRAF and NRAS mutations in melanomas arising in diverse internal organs.

Methods: Fifty-one melanomas from various internal organs were investigated for BRAF and NRAS mutation by direct DNA sequencing.

Results: BRAF and NRAS mutations were found in two and five mucosal melanomas arising from the aerodigestive and female genital tracts (n = 36). Their occurrence is mutually exclusive, giving a combined mutation incidence rate of 19.4% in mucosal melanomas. Both BRAF and NRAS mutations were absent in malignant melanoma of soft parts (n = 7). BRAF mutation was also absent in uveal melanoma (n = 6), but was seen in two of five cutaneous melanomas. The incidence of BRAF or combined BRAF/NRAS mutations in all non-cutaneous groups was significantly lower than published rates for cutaneous melanomas.

Conclusion: Each melanoma subtype may have a unique oncogenic pathway of tumour development, and only a small fraction of non-cutaneous melanomas may benefit from anti-RAF treatment.

Melanoma arises from the malignant transformation of pigment-producing cells, the melanocytes. Melanocytes originate in the neural crest and migrate to the basal layer of the epidermis and the hair follicles during embryogenesis. Apart from the skin, melanocytes are also found in most squamous covered mucous membranes, the uveal tract in the eye, and the leptomeninges of the brain. Thus, malignant melanomas can be classified by their site of origin into cutaneous melanoma, mucosal melanoma, uveal (ocular) melanoma, and leptomeningeal melanoma. Interestingly, malignant melanoma can also arise in sites not known to harbour melanocytes. This tumour is characterised by nests of malignant cells with a morphological and immunohistochemical profile of melanocytic differentiation, arising in tendons or aponeuroses in the extremities of young adults. Despite a common neural crest origin, the different subtypes of melanoma are distinct in their age of onset, aetiology, and biological behaviour. For example, cutaneous melanoma and malignant melanoma of soft parts tend to have an earlier age of onset compared with the other groups. Uveal melanoma tends to spread via the haematogenous route, whereas cutaneous melanoma shows a greater preference for lymphatic metastasis. Cutaneous melanoma is by far the most common and most well-studied subtype, constituting 90% of all cases. Whereas the development of most cutaneous melanomas is strongly linked to exposure to ultraviolet (UV) irradiation, the aetiology of non-cutaneous melanoma remains obscure. Moreover, melanomas arising from different sites may be heterogeneous in their molecular pathway of tumour development. For example, chromosomal aberrations such as monosomy of chromosome 3 and gain of 8q are common in uveal but rare in cutaneous melanoma. Conversely, alteration of the CDKN2 locus on 9p21 is common in cutaneous but rare in uveal melanoma. The (t(12;22)(q13;q12) translocation, resulting in a fusion gene product combining the 5' region of the EWS gene and the 3' region of the ATF1 gene, is found in 80% of malignant melanomas of soft parts, but not in other types of melanoma. Unfortunately, because of their relatively low incidence, genetic changes remain poorly defined for most non-cutaneous melanomas. With the recent development of pathway specific drug targets, defining these genetic changes in various subtypes of melanoma may have important therapeutic implications.

Interestingly, malignant melanoma can also arise in sites not known to harbour melanocytes.

It has long been known that activation of the RAS–RAF–MEK–ERK–MAPK (mitogen activated protein kinase) pathway plays an important role in cutaneous melanoma development. This involves an activating mutation of NRAS, which is found in over 20% of cutaneous melanomas. More recently, our group has described a high frequency of an activating BRAF mutation (more than 60%) in melanoma cell lines and human tumour samples. BRAF is a serine/threonine kinase that transduces regulatory signals from RAS through MEK to MAPK in the RAS–RAF–MEK–ERK–MAPK signalling cascade. Subsequent studies by

Abbreviations: MAPK, mitogen activated protein kinase; PCR, polymerase chain reaction; UV, ultraviolet
others have confirmed these results, and have shown that BRAF mutation is also present in a high percentage (82%) of cutaneous melanocytic naevi. Over 80% of the mutations involve a single base substitution in the kinase domain (T1799A), leading to a V600 amino acid substitution (nucleotide and codon numbers based on NCBI gene bank nucleotide sequence NT_007914, corresponding to T1796A, V599E in the old gene bank sequence NM_004333). We have nucleotide sequence NT_007914, corresponding to T1796A, (nucleotide and codon numbers based on NCBI gene bank (T1799A), leading to a V600E amino acid substitution in the kinase domain that could transform NIH3T3 cells. More recently, V599E in the old gene bank sequence NM_004333). We have

Three recent studies have also demonstrated a low incidence of BRAF mutation in melanoma arising from non-hair bearing (glabrous) skin that is relatively protected from UV damage because of the thickened cornified layer, and in melanoma arising from mucosa that is totally sun protected. Studies of the molecular changes in non-cutaneous melanomas could help to clarify their genetic pathway of development, which may be distinct from cutaneous melanoma. Furthermore, these results may have important therapeutic implications because those with BRAF mutations may benefit from specific treatment using a RAF inhibitor. Here, we analysed a large series of non-cutaneous malignant melanomas arising from various internal organs, including malignant melanoma of soft parts, which has not been studied before, for BRAF and NRAS mutations.

METHODS

Materials
We searched the computerised pathology records of the department of pathology of Queen Mary Hospital and Queen Elizabeth Hospital, Hong Kong from 1993 to 2003. The clinical and pathology records of all patients with a diagnosis of malignant melanoma or malignant melanoma of soft parts (also named clear cell sarcoma of tendon and aponeurosis) were retrieved for review. Patients with a diagnosis of primary non-cutaneous malignant melanoma or metastasis were selected for our present study. All except five cutaneous malignant melanomas or documented metastasis from cutaneous melanoma were excluded. The five cases of cutaneous melanoma or distant metastasis were randomly selected and included as controls for our mutation detection method and potential ethnic differences because most of our patients were of Chinese origin. This study was approved by the ethics committee of the University of Hong Kong.

In total, 56 malignant melanomas from various organ sites were finally selected. Table 1 lists in detail their anatomical site of origin. The histological slides were reviewed and appropriate paraffin wax embedded tissue blocks were retrieved. Sections (6 μm thick) were cut and stained with 0.1% methylene blue. Areas of the malignant melanoma were microdissected under a light microscope for DNA extraction using standard protocols, as described previously.

Mutation detection of BRAF and NRAS

Primers were designed to amplify exons 11 (G loop region) and 15 (activation segment) of BRAF, and exons 1 and 2 of NRAS. The primers for BRAF were the same as those used in our previous study. The primer sequences were as follows:

- BRAF exon 11F: 5'-TTCTGTGGGCTTGACTGCTT-3'
- BRAF exon 11R: 5'-'ACTGGTCACAATGTCACCACATT-3'
- BRAF exon 15F: 5'-TCATAATGCTTGCTCTGATAGGA-3'
- BRAF exon 15R: 5'-GGCCAAAAATTAATCAGTGGA-3'
- NRAS exon 1F: 5'-GGTTTCACAGGTTCCTGC-3'
- NRAS exon 1R: 5'-CAGTGGGCTCACCCTCTATG-3'
- NRAS exon 2F: 5'-CACACCCCCAGGATTCTTC-3'
- NRAS exon 2R: 5'-'TGCAATAATCAGAGGAAGC-3'

Polymerase chain reactions (PCRs) were performed in 20 μl reactions containing 0.5μM of each primer, 2.5mM Mg²⁺, 0.25mM dNTPs, and 1 U of AmpliTaq Gold DNA polymerase (Applied Biosystems, Foster City, California, USA) in 1x PCR buffer. In total, 40 amplification cycles (95°C for 30 seconds, 55°C for 30 seconds, and 72°C for 45 seconds) were performed with an initial denaturation at 95°C for 10 minutes and a final extension at 72°C for 10 minutes. The PCR products were purified with 1 μl Exol SAP (37°C for 15 minutes, then 85°C for 15 minutes) and were then sequenced directly on both strands using the BigDye® Terminator v1.1 cycle sequencing kit (Applied Biosystems) according to manufacturer’s protocol and analysed by the Applied Biosystems 3730 DNA analyser. All mutations were re-confirmed by independent PCR reactions and direct sequencing.

Statistical analysis

The differences in incidence of BRAF mutations or combined BRAF/NRAS mutations in our series of non-cutaneous melanomas (malignant melanoma of soft parts, mucosal melanoma, and uveal melanoma) were analysed in comparison with the cumulative incidence from all major published series of primary cutaneous melanomas using Fisher’s exact test.
NRAS mutation was found in five of 36 mucosal melanomas. This is also comparable to a previous study, which recorded NRAS mutations in four of 28 mucosal melanomas. In our present study, BRAF and NRAS mutations were mutually exclusive; thus, overall seven of the 36 mucosal melanomas had activation of the RAS–RAF–MEK–ERK–MAPK pathway through either BRAF or NRAS mutation. To our knowledge, this is the first comprehensive study that has characterised both BRAF and NRAS mutations in mucosal melanomas. The combined incidence of BRAF and NRAS mutations is significantly lower (p < 0.0001) than that seen in cutaneous melanomas (table 2).

We found a complete absence of BRAF or NRAS mutations in the seven malignant melanomas of soft parts, which is significantly different from cutaneous melanomas (p < 0.0001). This is the first systematic study of BRAF and NRAS mutation for this type of melanoma. Malignant melanoma of soft parts constitutes a distinct subgroup of malignant melanoma with an intriguing histiogenesis and molecular pathway of tumour development. These tumours tend to occur in deep tendons and aponeuroses, where melanocytes are not known to exist normally, and there is no involvement of the overlying skin. They have the same immunohistochemical profile as cutaneous melanomas—expression of the melanocytic markers HMB45 and S100 protein—the latter highlighting their neural crest origin. Intracellular melanin, although scanty, can be demonstrated in more than 50% of cases. The prognosis is generally poor, with a high propensity for recurrence and metastasis. Recurrence may sometimes occur after a long latent period of 10 or more years. The characteristic genetic change in these tumours is the t(12;22)(q13;q12) translocation, resulting in the expression of a fusion EWS–ATF1 transcript, which has not been found in cutaneous melanoma. In this respect, translocation involving the EWS gene is also involved in the development of several sarcomas, including Ewing’s sarcoma and primitive neuroectodermal tumour. BRAF mutations are extremely rare in sarcoma, and were seen in only one of 182 (0.5%) cases in our previous mutation screening. The rarity of BRAF or NRAS mutations in malignant melanoma of soft parts and the common occurrence of translocation involving the EWS gene suggest that this tumour is more closely related to sarcoma than cutaneous melanoma in its oncogenic pathway. Interestingly, both BRAF and the EWS–ATF1 fusion gene are involved at different points along the cAMP responsive pathway, which plays an important role in regulating the differentiation and melanogenesis of melanocytes. Whereas BRAF mediates the cAMP dependent activation of ERKs in melanocytes, the EWS–ATF1 chimaeric protein can function as a potent constitutive activator of several cAMP inducible promoters. It would be interesting to study whether the EWS–ATF1 fusion gene product and mutant BRAF have similar biological roles in melanoma onogenesis, which could help to explain the absence of BRAF mutations in malignant melanoma of soft parts.

Take home messages

- In contrast to cutaneous melanoma, we found a low incidence of BRAF and NRAS mutations in mucosal melanoma arising from the aerodigestive and female genital tracts, and a complete lack of these mutations in malignant melanoma of soft parts.
- Each subtype of melanoma may have its own unique genetic pathway of development, and only a small proportion of patients with non-cutaneous melanoma may benefit from anti-RAF specific treatment.

*Comparison of each category against primary cutaneous melanomas using Fisher’s exact test.

The difference in the incidence of BRAF mutation among different subtypes of malignant melanomas is intriguing. BRAF mutation appears to play an important role in regulating the growth of melanocytes and malignant transformation in the cutaneous compartment. Up to 80% of benign naevi of various histological types, including compound naevi, juncional naevi, and congenital naevi, harbour BRAF mutations. However, it should be noted that most benign naevi are end stage lesions and do not progress to malignant melanoma. In contrast, a study of cutaneous melanoma revealed a low incidence of BRAF mutation (10%) at the radial growth phase, but a high incidence (63%) in the vertical growth phase, which suggests that BRAF mutation does not occur at the initiation of tumorigenesis but is important in the progression of cutaneous melanoma. It has been suggested that the difference in incidence of BRAF mutations in different subtypes of melanoma could be related to aetiological factors such as ultraviolet exposure.”
61 involving a TT pyrimidine doublet and its 3’ nucleotide—the most frequent hotspot mutation of BRAF involves a T to A mutation, which is not typical of UV induced mutation. Moreover, a similar mutation spectrum for NRAS genes was found in some of the melanomas arising from internal organs, which are clearly not related to UV exposure. Thus, other environmental or intrinsic biological factors should also be considered as potential causative agents for these mutations in melanomas.

In summary, we have documented a low incidence of BRAF and NRAS mutation in mucosal melanoma arising from the aerodigestive and female genital tracts. Moreover, BRAF and NRAS mutation are totally absent in malignant melanoma of soft parts. These data suggest that each subtype of melanoma have its own unique genetic pathway of development, and only a small proportion of patients with non-cutaneous melanoma may benefit from anti-RAF specific treatment.
