ABSTRACT

Background Coronavirus disease-2019 (COVID-19) has caused a great global threat to public health. The World Health Organization (WHO) has declared COVID-19 disease as a pandemic, affecting the human respiratory and other body systems, which urgently demands for better understanding of COVID-19 histopathogenesis.

Objective Data on pathological changes in different organs are still scarce, thus we aim to review and summarise the latest histopathological changes in different organs observed after autopsy of COVID-19 cases.

Materials and methods Over the period of 3 months, authors performed vast review of the articles. The search engines included were PubMed, Medline (EBSCO & Ovid), Google Scholar, Science Direct, Scopus and Bio-Medical. Search terms used were ‘Histopathology in COVID-19’, ‘COVID-19’, ‘Pathological changes in different organs in COVID-19’ or ‘SARS-CoV-2’. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2009 guidelines were used for review writing.

Result We identified various articles related to the histopathology of various organs in COVID-19 positive patients. Overall, 45 articles were identified as full articles to be included in our study. Histopathological findings observed are summarised according to the systems involved.

Conclusion Although COVID-19 mainly affects respiratory and immune systems, but other systems like cardiovascular, urinary, gastrointestinal tract, reproductive system, nervous system and integumentary system are not spared, especially in elderly cases and those with comorbidity. This review would help clinicians and researchers to understand the tissue pathology, which can help in better planning of the management and avoiding future risks.

INTRODUCTION

Coronavirus disease 2019 (COVID-19), which is zoonotic in origin and most commonly spread through respiratory droplets or aerosol transmission, has caused a big threat to mankind. The disease was originated in the seafood market of Wuhan, Hubei, China, in early December 2019 with clinical presentations greatly resembling viral pneumonia. This disease has affected most of the countries in the period of 2 months itself. The outbreak of COVID-19 has been declared a pandemic by World Health Organization (WHO) and presents a great challenge for the healthcare communities across the globe.

The presently identified causative agent for COVID-19, severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), has shared 82% genome sequence similarity to previously identified SARS-CoV-1, which also originated in China in 2002. The structure of the enveloped single-stranded RNA virus consists of spike protein, which is mainly responsible for the pathogenesis in the human species. The spike protein of the virus, through its receptor binding domain (RBD) gets attached to a human cell surface receptor protein Angiotensin Converting Enzyme -2 (ACE-2), encoded by the ACE2 gene, followed by its priming through auxiliary protein TMPRSS2 (transmembrane protease, serine 2), a cell-surface protein that is expressed by epithelial cells of specific tissues including those in the aerodigestive tract. ACE-2, which acts as a viral host cell entry receptor, has ubiquitous distribution on the organs, therefore SARS-CoV-2 in severe cases causes a systemic disease, with possible involvement of the kidneys, the heart and blood vessels, the liver, the pancreas and also regulates alterations in circulating lymphocytes and the immune system. 

The maximum expression of the ACE-2 receptors according to the consensus dataset from the human protein atlas is found in small intestine, duodenum and colon followed by kidney, testis, gall bladder, heart, thyroid gland, adipose tissue, rectum and lungs.

The lungs are affected the most, with patients presenting symptoms related to the respiratory system such as sore throat, fever, malaise, and respiratory distress, and in worst cases may proceed to respiratory failure. Mice-related studies show that there is no gender difference in ACE-2 activity in lungs and heart but an expression of ACE-2 is more in male kidneys as compared with female kidneys, making the males more prone to kidney-related disorders, due to SARS infection.

The entry of virus in the host cells induces immune response with wide secretion of inflammatory cytokines and chemokines. Because SARS-CoV-1 and SARS-CoV-2 have the same mechanism of action, both can cause rapid production of multiple cytokines in body fluids following infection, leading to acute respiratory distress and multiple organ failure. This also explains why most patients with COVID-19 have mild symptoms at the onset of the disease, while conditions of a few affected patients are suddenly worsened.

| 1.   | ► Alveoli: Damaged or atypical enlarged pneumocytes with large nuclei, type II pneumocyte hyperplasia, diffuse alveolar damage (DAD), focal sloughing, hyaline membrane formation, intra-alveolar haemorrhage, intra-alveolar neutrophil infiltration, amorphophilic granular cytoplasm and prominent nuclei characteristic of viral cytopathic-like changes.  
▼ Vessels: Oedematous and congested vessels, plug formation, fibrinoid necrosis of the small vasculature, hyaline thrombi in microvessels. Significant deposits of complements—C5b-9 (membrane attack complex), C4d, and mannose binding lectin (MBL)-associated serine protease (MASP)-2, in the microvasculature.  
▼ Cellular components: Presence of syncytial giant cells, focal infiltration of immune and inflammatory (lymphocytes and monocytes) and increased stromal cells.  
▼ Ultrastructural changes: Viral particles in bronchial mucosal epithelia and type II alveolar epithelia. | Tian et al, Barton et al, Xu et al, Luo et al, Yao, Magro et al, Bradley et al                      |
| 2.   | ► Glomerulus: Ischaemic changes, podocyte vacuolation, focal segmental glomerulosclerosis, accumulation of plasma in Bowman’s space.  
▼ Renal tubules: Loss of brush border in proximal tubule, non-isometric vacuolar degeneration, and necrosis, oedematous epithelial cells.  
▼ Vessels: Erythrocyte aggregates obstructing the lumen of capillaries without platelet or fibrinoid material with occasional hemosiderin granules and pigmented casts, hyalinosis of arteriole, arteriosclerosis of medium sized arteries, fibrin thrombus, shrinkage of capillary loops in glomeruli.  
▼ Ultrastructural changes: Clusters of viral particles with distinctive spikes in the tubular epithelium and podocytes. | Yao et al, Su et al, Tietäväinen et al, Grimes et al, Bradley et al                                |
| 3.   | ► Liver: Focal macrovesicular steatosis, nuclear glycogen accumulation in hepatocytes, dense atypical small lymphocytes in portal tracts. Regenerative nodules and thick fibrous bands, mild zone 3 sinusoidal dilatation, mild lobular lymphocytic infiltration. Patchy hepatic necrosis in the perportal and centrilobular areas. Hepatic cell degeneration and focal necrosis, biliary plugs in the small bile duct.  
▼ Oesophagus: Occasional lymphocytic infiltration in the oesophageal squamous epithelium.  
▼ Stomach: Partial epithelial degeneration, necrosis and shedding of the gastric mucosa. Dilatation and congestion of small blood vessels and oedema of lamina propria and submucosa with infiltration of immune cells (as lymphocytes, monocytes, and plasma cells).  
▼ Intestine: Stenosis of the small intestine and segmental dilatation. Numerous infiltrating plasma cells and lymphocytes with interstitial oedema in the lamina propria.  
| 4.   | ► Foci of lymphocytic inflammation.  
▼ Acute myocyte necrosis.  
▼ Presence of inflammatory cells and apoptotic bodies.  
▼ Ultrastructural observation: Viral inclusion bodies in vascular endothelial cells.  
| 5.   | ► Thickened basement membrane with peritubular fibrosis and vascular congestion.  
▼ Leucocyte infiltration.  
▼ Extensive germ cell destruction.  
▼ TUNEL assay: Increased apoptotic spermatogonial cells. | Jian Xu et al, Chen et al                                                                         |
| 6.   | ► Acute hypoxic ischaemic injury, hyperaemia, oedema and neuronal degeneration.  
▼ CT, MRI: Ischaemia and/or haemorrhage, and enhanced cortical/subcortical grey matter and fibre tracts.  
▼ SARS-CoV-2 RNA was detected in the brain tissue and cerebrospinal fluid in some patients. | Solomon et al, Mahammedi et al, Moriguchi et al                                                   |
| 7.   | ► Vessels: Perivascular inflammatory cells, intraluminal thrombi.  
▼ Epidermis: Parakeratosis, acanthosis, dyskeratotic keratinocytes, necrotic keratinocytes, acantholytic clefts, lymphocyte satellitosis and pseudoherpetiform.  
▼ Immunohistochemistry: ACE-2 positivity in basal layer of cells in hair follicle, sebaceous glands, smooth muscle cells. | Hamming et al, Gianotti et al, Kolivras et al                                                   |

after being diagnosed in hospital, which may be related to the body producing excessive cytokines after the disease, leading to ‘cytokine storm’ in the body. The association of viral infection with any comorbid conditions such as hypertension, diabetes and renal failure has shown more severe form of clinical presentations such as respiratory failure to multiple organ failure.  
To understand the effects, presenting symptoms and the pathophysiology of SARS-CoV-2 on various organs, it is of utmost need to understand the pathological findings related to the coronavirus disease, depending on the localisation of the ACE-2 receptors in various organs.

MATERIALS AND METHODS

Objective

Data on histopathological changes in different organs are still scarce, thus we aim to review and summarise the latest histopathological findings observed in different organs related to the infection following autopsy of patient’s corpse who died following SARS-CoV-2 infection.

Information sources and search strategy

Over the period of 3 months, the authors performed vast review of the articles. The search engines used included PubMed,
In this review, authors identified various articles related to the histopathology of different organs in COVID-19 positive patients. Overall, 45 articles were identified using different databases as full articles to be included in our study. Histopathological findings observed are summarised according to the systems involved.

Pathological features
The early pathological findings identified in the COVID-19 suggested that SARS-CoV-2 can widely spread in the epithelial lining of the respiratory tract, digestive tract, distal convoluted tubules of the kidney, the sweat glands of the skin and testicular epithelium including spermatogonia and sertoli cells. Now, it has been found that, in addition to respiratory transmission, the virus might also be transmitted through faeces, urine and skin. The new findings have also necessitated new ways to prevent the transmission of disease. Many studies on epidemiology and clinical characteristics of COVID-19 have been published but data on pathological changes in different organs are still scanty. Hence, the histopathological findings in details have been described below according to the body systems involved.
Histopathological findings in respiratory system

Patients with affected upper respiratory tract usually present with mild to moderate symptoms but patients with lower respiratory tract infection show features of pneumonia and land up with organ failure. The severity increases with presence of comorbidities like hypertension, chronic kidney disease, obstructive sleep apnoea and metabolic diseases like diabetes and obesity, \(^1\) and the pathological changes may even vary between right and left lung. \(^2\) Macroscopically, lungs appear congestive, with patches of haemorrhagic necrosis. \(^3\) Alveolitis with atrophy, vascular degeneration, proliferation, desquamation and squamous metaplasia of alveolar epithelial cells (figure 1A), with presence of exudative monocytes and macrophages (figure 2F) are prominent features microscopically. There may be presence of massive fibrinous exudate, multinucleate giant cells and intracytoplasmic viral inclusion bodies and presence of epithelial cells in the lumen suggesting necrotic changes (necrotising bronchiolitis). \(^1\) There may be presence of diffuse alveolar damage (DAD), hyaline membrane formation and vascular congestion with occasional inflammatory cells, damaged pneumocytes with focal sloughing and formation of syncytial giant cells, along with focal infiltration of immune cells in the form of lymphocytes, monocytes and increased stromal cells (figure 1A). \(^2\) Additional findings included intra-alveolar haemorrhages, cluster or plug formation due to the accumulated fibrin (figure 1D) and degraded hyaline membrane remnants in some of the alveoli, type II pneumocyte hyperplasia, fibrinoid necrosis of the small vasculature and abundant intra-alveolar neutrophil infiltration (suggestive of superimposed bacterial infection) leading to bronchopneumonia (figure 1F). \(^3\) There may be presence of patchy and sparse chronic inflammation, composed mainly of lymphocytes, along with thrombi in branches of pulmonary artery and focal areas of congestion in alveolar septal capillaries along with septal capillary injury with mural and luminal fibrin deposition. \(^4\) \(^5\) Inflammatory oedema in the respiratory mucosa \(^6\) along with CD3+, CD4+ T cells, CD20+ B-lymphocytes and presence of CD68+ macrophages highlight the presence of inflammatory changes. \(^6\) \(^7\) There is also evidence of significant deposits of terminal complement components C3b-9 (membrane attack complex), C4d, and mannose binding lectin (MBL)-associated serine protease (MASP)-2, in the microvasculature, consistent with sustained, systemic activation of the alternative and lectin-based complement pathways. \(^8\) Pneumocytes may contain the

Figure 3 Histopathological changes in kidneys of COVID-19 patients

(A) Epithelium of proximal convoluted tubules shows decreased/loss of the brush border. (B) Tubular epithelial cells show vacuolar degeneration (arrows), leading to collection of necrotic debris in the lumen (asterisks). Blocked peritubular capillaries due to erythrocytic aggregates (arrowheads). (C,D) Inflammatory cells (arrowhead) infiltrate the tubules and arcuate artery (arrow). Bacterial foci (asterisks) is also observed. (E,F) Tubular deposition of hemosiderin granules, calcium deposits (arrowhead) and pigmented cast (arrow). (G,H) Glomeruli show ischaemic contraction (arrows) and fibrin thrombi (arrowhead). Bowman’s space show presence of leaked accumulated plasma; hematoxylin and eosin. Bars = (F) 50 μm, (A–C, E, G, H)100 μm, and (D) 250 μm. (Courtesy: Su H, Yang M, Wan C, Yi L-X, Tang F, Zhu H-Y, et al. Renal histopathological analysis of 26 postmortem findings of patients with COVID-19 in China. Kidney Int. 2020 Jul;98(1):219–2.)

---

Figure 4 (A) Hepatocytes showing glycogenated nuclei and atypical small lymphocytes densely infiltrating the area of portal triad and showing CD20 positivity (inset). Dense portal infiltration by atypical small lymphocytes (inset: CD20 immunostaining) and focal glycogenated nuclei in hepatocytes have also been observed. (B) Hepatic nodules showing fibrosis, indicative of cirrhosis. Cirrhotic nodules with thick fibrosis. (C) Hepatic sinusoids are dilated and filled with lymphocytes. Mild sinusoidal dilatation with increased lymphocytic infiltration. (D) High power view showing sinusoidal lymphocytes. (E,F) Periportal and centrilobular areas show necrosis, indicative of injury. (Courtesy: Tian S, Xiong Y, Liu H, Niu L, Guo J, Liao M, et al. Pathological study of the 2019 novel coronavirus disease (COVID) through postmortem core biopsies. Mod Pathol. 2020 Apr 14;1–8.)
virus within the cytoplasm and may show nucleomegaly and prominent nucleoli with small basophilic and larger eosinophilic cytoplasmic inclusions. Ultrastructural examination can reveal more details regarding the viral particles. Type II pneumocytes harbour numerous autophagosomes, characterised by double membranes and presence of organelles, in the cytoplasm (figure 2). These autophagosomes which contain viral aggregates, may also be present in tracheal epithelial cells and within the extracellular mucus in the tracheal lumen. Presence of virus particles has been shown by immunohistochemical staining using monoclonal antibody against SARS-CoV-2 nucleocapsid protein (figure 2C).15

Most of the histopathological findings are similar to those described in severe acute respiratory syndrome coronavirus-1 (SARS-CoV-1) and Middle East respiratory syndrome coronavirus (MERS-CoV).16 These data suggest similarities in the pathogenesis and the mechanisms of tissue damage in lung tissue and inflammatory response to coronavirus infections, highlighting that the successful methodology in managing SARS and MERS could be referred to patients with COVID-19. Microscopic study of the COVID-19 lung tissue raises a possibility that nasopharyngeal swab showing negative result might not reflect the actual viral load in lung tissue.13 This study is important for the clinicians and virologists dealing with patients with COVID-19 as this study provides the pathological evidence for residual virus in the lungs for a patient with three consecutive negative PCR test results for the virus. Hence, PCR detection of SARS-CoV-2 nucleic acid on bronchoalveolar lavage fluid, extension of quarantine time and timely follow-up medical examination on discharged patients, especially older or immunocompromised patients, should be preferred.
**Histopathological findings in urinary system (kidney)**

ACE-2 is found to be upregulated in patients with COVID-19, and immunostaining with SARS-CoV-2 nucleoprotein antibody is positive in tubules. In addition to the direct virulence of SARS-CoV-2, factors contributing to acute kidney injury (AKI) includes systemic hypoxia, abnormal coagulation and possible drug or hyperventilation-relevant rhabdomyolysis. In some patients, pigmented casts is observed to be associated with high creatine phosphokinase levels possibly representing rhabdomyolysis.

Clinically, the incidence of AKI in COVID-19 varies from 0.9% to 2% with new onset proteinuria. Microscopic changes in adult may range from diffuse proximal tubule injury with loss of brush border, non-isometric vacuolar degeneration to even frank necrosis. Other changes seen are swollen glomerular endothelial cells with small amount of protein exudate in the balloon cavity, and presence of thrombus in the capillaries, tubular epithelial cell oedema, vacuolar degeneration (figure 3A,B), with occasional cellular swelling and oedematous expansion of the interstitial spaces in distal collecting tubules and collecting ducts. Non-specific fibrosis along with lymphocytic infiltrates may be found beneath the renal capsule. Absence of interstitial haemorrhage or vasculitis differentiates this type of tissue injury from other causative factors like Hanta virus or injury by anti-neutrophil cytoplasmic antibodies. There can be presence of prominent erythrocyte aggregates, obstructing the lumen of capillaries, without platelet or fibrinoid material, with occasional hemosiderin granules and pigmented casts (figure 3E,F). Electron microscopic (EM) examination shows clusters of viral particles with distinctive spikes, in the tubular epithelium and podocytes.

Microscopic changes associated with the comorbid conditions such as diabetes and hypertension show characteristic findings in glomeruli, which include nodular mesangial expansion and hyalnosis of arterioles (associated with diabetic nephropathy) and arteriosclerosis of medium-sized arteries with ischaemic glomeruli. Occasional findings include segmental fibrin thrombus, podocyte vaculization, focal segmental glomerulosclerosis and shrinkage of capillary loops with accumulation of plasma in Bowman’s space (ischaemic changes)(figure 3G,H).

**Histopathological findings in digestive system (liver)**

Although microscopic changes of hepatic tissue in COVID-19 have not been reported much, hepatic injuries cannot be ignored as the ACE-2 receptors have also been detected in the hepatobiliary system where cholangiocytes (59.7%) showed higher expression of ACE-2 cell surface receptor compared to hepatocytes (2.6%). Considering the fact that cholangiocytes expressed ACE-2 in the same manner as the type-2 alveolar cells, there is every possibility for the liver to be a potential target for SARS-CoV-2. Besides, concomitant use of medications also has effect on the hepatobiliary system. Hepatic injury mostly occurs in those with moderate to severe illness.

Hepatic cell degeneration and focal necrosis in addition to presence of some biliary plugs in the small bile duct has been observed in light microscopic study. Although endothelial cells show positive ACE-2 expression, the endothelial lining of the liver sinusoids may be negative for ACE-2 along with Kupffer cells and hepatocytes. However, it cannot be denied that apart from the SARS-CoV-2 infection, parallel use of hepatotoxic drugs, pre-existing chronic liver disease and COVID-19 related hyperinflammatory conditions can lead to hepatic injury, particularly when the patient is in hypoxic state. Microscopically, a liver, injured due to SARS-CoV-2 infection, may show signs of cirrhosis and regeneration with macrovesicular steatosis and glycogen accumulation in the liver cells along with atypical lymphocytic infiltration in the portal tract (figure 4A,B). Sinusoidal dilatation in zone 3, mild lymphocytic infiltration and patchy hepatic necrosis have also been observed in the area of portal triad and centrilobular areas (figure 4E,F).

**Histopathological findings in gastrointestinal tract**

Common gastrointestinal symptoms with which COVID-19 positive patients presented were diarrhoea, decreased appetite, nausea, vomiting, abdominal pain and gastrointestinal bleeding during the onset and subsequent hospitalisation.

There are pieces of evidence of stenosis of the small intestine and segmental dilatation along with varying degrees of degeneration, necrosis and shedding in the gastrointestinal mucosa. Gastric tissue may show epithelial degeneration, necrosis and shedding of the mucosa with the presence of dilated and congested small blood vessels in lamina propria and submucosa along with infiltration of lymphocytes, monocytes and plasma cells. Endocrine pancreas may show evidence of tissue degradation. However, mucosal epithelial cells of the gastrointestinal tract may be apparently normal with occasional inflammatory infiltrates.

**Histopathological findings in cardiovascular system**

Cardiac pathology

Viral infections being one of the most common causes of infectious myocarditis, cardiac involvement by SARS-CoV-2 cannot be ruled out. Endomyocardial biopsy from a 69-year-old COVID-19 positive patient, who died of septic shock, depicted low-grade myocardial inflammation and viral particles in the myocardial interstitial cells but not in cardiomyocytes or endothelial cells. However, involvement of cardiomyocytes cannot be ruled out as there are reports of hypertrophied cardiomyocytes along with inflammatory infiltrates, focal oedema, interstitial hyperplasia, fibrosis, degeneration, necrosis and signs of lymphocytic myocarditis. Besides ultrastructural changes like swelling of myocardial fibres, myocardium also shows presence of CD4 T cells along with other inflammatory infiltrates. However, pre-existing morbidity cannot be ruled out like hypertension-associated myocardial hypertrophy and past ischaemic injury.

Endomyocardial biopsy from non-ischaemic heart showed endocarditis and inflammation of interstitial tissue and viral particles have been observed in interstitial cells with damaged cell membrane, but myocytes were apparently normal with no viral particles. Viral particles may be absent while other signs of inflammation may be present within the cardiac tissue like leucocyte infiltration and presence of CD4+ T cells indicating indirect injury to the cells by the virus.

Blood vessels

Due to the presence of ACE-2 receptor in the vascular endothelial cells, these are easy target for the SARS-CoV-2 virus. Studies show presence of viral inclusions along with inflammatory cells and apoptotic bodies in the endothelial cells. There are pieces of evidence of oedematous changes in alveolar capillaries and small vessels with the presence of fibrin thrombi, neutrophils and CD61+ megakaryocytes. Histological findings in purpuric papulovesicular rash of skin showed dense perivascular lymphocytic infiltration around the swollen blood vessels.
with extravasation of red blood cells. While punch biopsy from a case showed plump endothelial cells in lymphoplasmacytic infiltrate surrounded venules without intraluminal thrombi.

**Histopathological findings in nervous system**

Neurological symptoms in COVID-19 have been frequently reported; however, the histopathological studies that investigated central nervous system (CNS) lesions are currently very limited. Dizziness and headache were most common CNS manifestations, while taste and smell impairment were the most common peripheral nervous system symptoms. Stroke, acute encephalopathy, convulsions, ataxia or nerve demylation symptoms were occasional neurological presentations in some patients. Based on the analysis of spectrum of neurological symptoms, possible routes of CNS entry for SARS-CoV-2 virus have been proposed through the hematogenous route by breaching blood–brain barrier or retrograde neuronal spread involving olfactory nerves. Olfactory route of viral entry into CNS were shown in mice models of SARS-CoV-1 and MERS-CoV which also showed widespread brain lesions following olfactory inoculation of the virus; however, no such evidence is specifically available at present for SARS-CoV-2. A recent postmortem examination study in patients with COVID-19 who displayed neurological symptoms showed widespread brain lesions. Autopsied brain tissue showed signs of acute hypoxic ischaemic injury like hypoaemia, oedema and neuronal degeneration. Neuroimaging scans (CT and MRI) for patients with COVID-19 presenting with acute neurological symptoms showed signs of ischaemia and/or haemorrhage, and enhanced cortical/subcortical grey matter and fibre tracts. SARS-CoV-2 RNA was detected in the brain tissue and cerebrospinal fluid of some autopsied patients with COVID-19 who had presented with neurological symptoms.

**Histopathological findings in genital system (testis)**

Evidence has been found between the association of coronavirus family and orchitis in humans. ACE2 is present in seminiferous tubules, leydig cells, sertoli cells and spermatogonia. Binding of the virus with the testicular cells expressing ACE2 receptors not only damages the testicular tissue but also forms a potential safehouse for the virus. These hidden hotbeds for the virus may form an important cause for infertility worldwide.

Studies show that sertoli cells are more susceptible than germ cells as more than 90% of the sertoli cells expressed ACE-2 receptors. Also, spermatogonia stem cells show higher expression of TMPRSS2 but lower expression of ACE-2, while the sertoli cells show higher expression of ACE-2 but lower expression of TMPRSS2, suggesting the mutual role of spermatogonia and somatic cells or sertoli cells for the invasion of the virus. All SARS-infected testes demonstrate histological findings with extensive germ cell destruction and decreased spermatogenesis in the seminiferous tubules. The basement membrane gets thickened with peritubular fibrosis along with leucocyte infiltration and vascular congestion in the interstitial tissue. Sertoli cells show swelling, vacuolation and cytoplasmic rarefaction. TUNEL assay shows increased apoptosis in the spermatogenic cells and leydig cells of the SARS patients’ testes. One of the evident phenomena in the COVID-19 testis is leucocyte infiltration (figure 5D). These cells could affect the function of leydig cells and thus responsible for decreased production of testosterone (figure 5C). These infiltrated cells especially the lymphocytes and histiocytes, also damage the blood–testis barrier and destroy the seminiferous tubules directly (figure 5E,F).

Similar to other viruses like HIV, mumps and hepatitis B virus, SARS-CoV-2 also may lead to activation of inflammatory cytokines, which may potentiate the autoimmune response. They may cause orchitis by several mechanisms, which may result in the testicular damage leading to infertility and sterility, which may further increase the chances of testicular tumours. Hence, it is a point of concern for patients suffering from testicular cancers with superadded SARS-CoV-2 infection. According to Song et al, no positive RT-PCR result was found in the semen or testicular biopsy specimen, hence suggesting that possibly it will not be transmitted through the sexual route.

**Histopathological findings in skin**

The virus reaches the cutaneous tissue through the blood vessels. Since the endothelium abundantly expresses ACE-2, it can easily bind to the viral spike protein and facilitate viral invasion into the skin tissue thus initiating the pathogenesis. Inflammatory response caused by the viral invasion leads to inflammatory cell infiltrates, giving the pathological feature of vasculitis. Immune response leads to activation of Langerhans cells causing a cascade of reactions. With the usual common manifestations in COVID-19 positive cases, the dermatological manifestations may go unnoticed and a person may be a source of infection without his or her knowledge. As any other viral infection, the skin manifestations of a COVID-19 positive person may also show signs of erythematous rash, dermatis, urticaria, chicken pox-like vesicles purpuric papulovesicular rash which may even be painful, pseudo-chilblains on fingertips and toes, macular/maculopapular exanthems, livedo reticularis lesions, petechiae and so on (figure 6). Since there is no correlation with disease severity or duration, an apparently normal person with positive test may come with only dermatological complaints, with the dermatological lesions mostly in trunk, hands and feet, as they are the most exposed regions of the body. Most of the skin lesions heal without any residual signs. Knowledge of skin manifestation may aid in early diagnosis of an asymptomatic COVID-19 patient.

In the epidermis of the skin, the ACE-2 expression is observed in the stratum basale. ACE-2 expression has also been identified in smooth muscle cells of the skin along with the cells around the hair follicle. Although not very strong, the cytoplasm of the cells of sebaceous glands also expresses ACE-2 along with its strong expression in the cells of eccrine glands. Dense perivascular lymphocytic and plasmacytic infiltration has also been observed around the swollen blood vessels with extravasation of red blood cells and intraluminal thrombi. Parakeratosis, acanthosis, dyskeratotic keratinocytes, necrotic keratinocytes, acantholytic clefts along with lymphocytes satellitism have also been observed in biopsy samples of COVID-19 positive patients (figure 7). Presence of COVID-19 cutaneous manifestations may not be specific to SARS-CoV-2, but may be secondary to the various chains of events taking place due to the viral invasion. But keeping the features in mind will be a good approach towards determining the clinical value of the medical examinations required.

**CONCLUSIONS**

Information regarding the pathological findings in COVID-19 is limited, although the virus mainly affects respiratory and immune systems, but other systems like cardiovascular, urinary (kidneys), gastrointestinal tract, reproductive (testes) and nervous system are not spared, especially in elderly patients, more often if comorbidities are also present. This review would definitely help

---

clinicians and researchers to understand the tissue pathology, which can further help in better planning of the disease management and avoiding future health risks.
